Glossary

Alternating current (AC) Usually in the form of a sine wave, the bidirectional current flow continually reverses. Typically, AC will have a zero mean (average) and a nonzero RMS value. In the USA, most “grid” electricity is generated and distributed in the form of 60 Hz sinusoidal waveform. In other areas of the world, 50 Hz is commonly used.

Amp-hour (Ah) A unit of electric charge, the amount of current delivered for 1 hour.

Battery A group of one or more cells electrically connected in series and/or parallel combinations to achieve higher voltage or current than what is capable from a single cell.

Battery management system (BMS) An electronic device or system that monitors and controls a rechargeable battery. Parameters measured may

include cell temperature, voltage, and current. From this data, the BMS can compute the state of charge of the battery and estimate the state of health, remaining cycle lives, or remaining service life. Typically, a BMS system will include the ability to communicate with a host system and battery charger. The BMS may also contain sensors and circuitry for protection such as over-current, over-temperature, or over-voltage.

Battery pack A group of batteries or individual cells electrically connected in series and/or parallel combinations along with the required electrical interconnections, mechanical packaging, thermal management, and sensing circuitry. Because it is a self-contained assembly, a battery pack can be easily swapped in and out of the application.

Battery string Series-connected batteries used to produce a higher voltage. The same current passes through all the cells, but each cell voltage can vary. Charge balancing becomes a significant issue for a long string of 50 or more cells.

C-rate The rate at which a battery can deliver or accept current, stated in terms of the rated capacity of the cell in amp-hours. This may also be referred to as the hour rate, such as the 1-h rate.

Cell An individual electrochemical device that converts between chemical energy and electrical energy. The cell construction, open circuit voltage, energy, and power density, all depend on the chemistry of the cell (see section “[Battery Chemistries](#)”).

Coulombic efficiency Ratio of charge delivered by a rechargeable battery during discharge cycle to the charge stored during charge cycle.

Depth of discharge (DoD) An alternate method to indicate the state of charge of the battery; it is the reciprocal of SoC.

Direct current (DC) Unidirectional current that continually flows only in one direction. Sources such as batteries, fuel cells, and solar cells produce electricity in the form of direct current.

Memory effect An effect observed particularly in nickel cadmium batteries in which the cells gradually lose capacity when subject to repeated partial discharges followed by complete recharge cycles. This electrochemical effect is different than the loss of capacity due to aging and use. In some cases, a series of full discharge/recharge cycles can restore some or all of the lost capacity due to the memory effect but not due to cycle life or aging.

Proportional-integral (PI) controller A type of linear feedback control in which an error signal is calculated as the difference between a measured signal and the desired reference set point. The controller attempts to adjust the operation of the process using a weighted combination of the present error (proportional term) and accumulated past error (integral term).

Primary battery One-time-use batteries not capable of being recharged. They are discarded or preferably recycled once the stored energy has been depleted. These types of batteries will not be considered in this article.

Root mean square (RMS) A scalar quantity that is computed from the square root of the sum of the squares of a dataset and is commonly used to represent a voltage or current over one cyclical period. Average power is the product of the RMS current and RMS voltage.

Secondary battery Commonly referred to as rechargeable batteries, they can be repeatedly recharged electrically by passing current through them in the opposite direction to that of the discharge current. Secondary batteries are of significant interest for their ability to store and supply energy and are the focus of this article.

Self-discharge rate The rate at which a battery discharges, or loses stored energy, due to internal cell reactions.

SLI batteries Starting, lighting, and ignition (SLI) batteries are used in automobiles. These batteries are usually characterized by a high discharge rate.

State of charge (SoC) Defined as the capacity left in a battery expressed as a percentage of some reference. SoC of a battery is usually expressed as a percentage of the current battery capacity when it is fully charged.

State of health (SoH) A metric that reflects the general condition of a battery and its ability to deliver the specified performance compared with a fresh battery. It takes into account factors such as charge acceptance, internal resistance, voltage, and self-discharge. It is an estimate rather than a measurement.

Watt-hour (Wh) A unit of energy, the amount of power delivered for 1 h. It is equivalent to 3,600 Joules of energy.

Definition of the Subject

Batteries, both primary and rechargeable, are important energy storage devices ubiquitous in our daily, modern lives. Whether in our handheld portable electronics, conventional or hybrid/electric cars, or in the electrical “grid,” battery technology will continue to evolve as technology improvements increase storage capacity and lifetime and reduce cost.

Introduction

Batteries are perhaps most synonymous with portable power such as flashlights and personal electronics like cell phones, music players, and laptops to name a few modern examples. We have become trained to monitor the battery “bars” to determine how much more we can talk, e-mail, or surf the “net.” Batteries are far more prevalent, however, and they tend to be underappreciated, such as the ones in our automobiles which perform dutifully until suddenly, usually after years of neglect, they fail to start our car. An electrical power system is the ultimate in just-in-time manufacturing in that electricity generation and consumption must be perfectly balanced at all times. This imposes difficult operating constraints on the system when variability on both the load side and source side exists, such as with renewable energy sources like wind and solar. Therefore, energy storage is important to ensure that electricity can be generated and energy stored generated when the source is available, and the load can continue to be supplied when the variable, renewable energy source is insufficient. While there are many technologies for energy storage, batteries play an important role to improve the electric power system asset utilization, energy availability, reliability, and performance. Several large-scale, high-energy battery technologies hold

promise of providing economical energy storage for a wide range of these power system and energy management applications.

This chapter will discuss issues related to batteries, battery charging, and battery management. The first section will provide an overview of the different types of battery chemistries. The focus in this chapter is on rechargeable batteries which can accept, store, and then deliver energy at a future point in time. Subsequent sections will discuss circuits to charge and manage the batteries.

A detailed description of internal construction of the individual cell is beyond the scope of this chapter, but it is sufficient to consider that a battery is typically comprised of electrodes, electrolyte, and some form of case or enclosure as shown in Fig. 1. Various materials are commonly used, each with advantages and disadvantages. The voltage, current rating, and storage capacity are all functions of the material and construction.

Battery Failure

Some of the most common causes for battery failure are short circuiting of battery terminals, improper charge control while charging secondary batteries,

improper polarity connections while charging a battery, and a long period of use. Internal failure modes include thermal runaway which is a major problem in lead-acid batteries, loss of electrolyte by gassing, mechanical damage, and warping of plates due to an excessively high rate of discharge.

Methods of Charging

Float charge is most commonly used for non-sealed lead-acid batteries, which can tolerate sitting at an elevated voltage for prolonged periods of time. The original meaning of the term stems from the telecom industry's jar batteries in which the liquid electrolyte was exposed to the atmosphere and the batteries "sat on float" at a continuous elevated voltage to be sure they were fully charged when called upon to back up the telephone equipment. In this mode of operation, the charging current depends on the state of charge of the cells, and the current gradually declines to a minimum value as the cells become fully charged. Float charging could result in continuous out gassing which reduces the level of water in the electrolyte. Hence, float charging of lead-acid batteries often requires "watering" of the batteries to maintain the level of electrolyte.

Trickle charge is used to maintain a battery at a full state of charge by supplying a small current to offset the self-discharge characteristics of the battery. Some battery chemistries, like the lead-acid varieties, have relatively high self-discharge rates and can lose their ability to hold a charge when stored discharged for a long period of time due to sulfation, the crystallizing of the lead sulfate. A trickle charger, sometimes called a "battery tender" is often used in automobile, boats, motorcycles, RV and other seasonal equipment where the battery can sit for months without use.

Bulk charge involves restoring the majority of the energy storage capability of a battery. Hence, a bulk charge may be followed by an equalizing charge.

Equalization charge is the final stage of charging for a series-connected battery string in which the SoC of individual cells are forced to the same value. For lead-acid batteries, this can be as using a higher charging voltage. The cells with higher SoC begin to outgas while the weaker cells "catch up." Other battery chemistries

Batteries, Battery Management, and Battery Charging Technology. Figure 1

Conceptual illustration of a lead-acid battery with parallel, interleaved plate that comprises the anode and cathode. The electrolyte can be a liquid or a gel, and the enclosure can be vented or sealed

cannot tolerate overvoltage charging. Charge balancing techniques will be described in detail in the next section.

Rapid charge involves quickly recharging a battery at a high C-rate. Depending on the battery chemistry, this mode of charging may only replace a portion of the full capacity. It is usually imperative to monitor the cell temperature rise during rapid charging to avoid excessive outgassing or thermal runaway.

Regardless of the mode of charging, the charging types include constant-current charging and constant-current–constant-voltage charging (constant-current charge until current attains a flat profile, then constant-voltage charging takes over).

Battery Chemistries

A wide variety of battery electrochemistries are available today. While there is a clear evolution of technological progress, each technology has advantages and disadvantages that make them more or less suited for different applications. This section presents an overview of commonly available technologies and explores their general characteristics, advantages and disadvantages, and charging considerations.

Lead Acid

General Characteristics

Lead-acid batteries are by far the most common battery type and represent approximately 40–45% of the total global battery sales. Lead-acid batteries are available in large quantities and in a variety of sizes and designs. They are manufactured in sizes from smaller than 1 Ah to several thousand Ah. Design variations to electrode plates enable them to perform as batteries with high discharge rate and low-energy (automobile starting applications) and also for deep-cycle applications with moderate discharge rates.

The world's largest battery-based energy storage system is a 40-MWh battery located in Chino, California. It uses individual industrial-size lead-acid cells in series and parallel connection to make a 10-MW system capable of delivering energy into the utility grid at 2,000V and 8,000A for 4h.

Advantages and Disadvantages

Advantages include:

- One of the main reasons for the popularity of lead-acid batteries is that they can be manufactured on a local basis worldwide with high rates of production.
- Traditionally, they have been used as starting-lighting-ignition (SLI) batteries in automobiles, though now they are being slowly phased out by high-performing nickel cadmium and nickel metal hydride batteries.
- They have a high cell open-circuit voltage of 2.0 V which is one of the highest for aqueous electrolyte systems.
- SoC estimation is very easy in the case of lead-acid batteries. The specific density of electrolyte bears a direct relation to the SoC of the battery.
- It provides good charge retention for intermittent charge applications.
- Cell components can be easily recycled.
- They are very cheap compared to other secondary battery designs.
- They are also available in maintenance-free designs.

Disadvantages include:

- Lead-acid batteries require frequent maintenance. These batteries lose water while in operation, and the water level needs to be replenished.
- As they employ lead in their construction, they are usually heavy and not conducive for portability.
- Lead-acid batteries have a relatively low cycle life (50–500 cycles). However, up to 2,000 cycles have been achieved with cell design improvements, heavily derating the discharge capacity and using active charge equalization techniques (see section “[Cell Charge Equalization](#)”).
- One of the major drawbacks is the thermal runaway problem. It can occur due to improper design of battery or charger.

Application Examples Lead-acid batteries are commonly installed in uninterruptible power supply (UPS) systems, in renewable and distributed power systems. Traditionally, they were used as SLI batteries in automobiles. Other applications include telephone systems, power tools, communication devices, emergency lighting systems, and as the power source for mining and material-handling equipment.

Charging Characteristics Lead-acid batteries do not exhibit memory effect. However, it is very vital to have the correct charge and float voltages to achieve a long life. Charging up to the rated voltage level is a must; any deviation from this voltage level leads to electrode corrosion or negative plate sulfation in the long run. Lead-acid batteries used for deep-cycle applications usually have a short life of about 300 discharge/charge cycles.

Lead-acid batteries are typically charged in three stages, which are constant-current bulk charge, equalization final charge, and float charge. The *constant-current charge* provides bulk of the charge and takes up about half of the required charge time. The *equalizing charge* continues charging at a lower charge current and ensures all cells are fully charged and the state-of-charges are similar. This may be done through active techniques or simply overcharging some cells to ensure the undercharged ones receive a full charge. The *float charge* compensates for the self-discharge loss when a battery sits unused for a period of time.

Valve-Regulated Lead Acid (VRLA)

General Characteristics The valve-regulated lead-acid (VRLA) battery is a completely sealed cell, which prevents electrolyte loss due to outgassing, and hence alleviates the need to water the cells. The VRLA battery incorporates the gas recombination principle which allows the oxygen generated at normal overcharge rates to be reduced at the negative plate, eliminating oxygen outgassing. If the rate of outgassing exceeds the rate of recombination, the partial pressure of hydrogen builds up and can cause the vent to open, which destroys the cell.

Advantages and Disadvantages

Advantages include:

- VRLA batteries do not require “watering” as is the case with other types of lead-acid batteries since the water level is maintained due to a regenerative cell reaction. Thus, VRLA batteries do not require the frequent maintenance for battery operation, which is an advantage over the conventional lead-acid battery.
- Battery cells can be packaged more tightly because of sealed construction and immobilized electrolyte, hence the footprint and weight of the battery are reduced.

- SoC is measured by measuring the voltage (The open-circuit voltage can therefore be used to approximate the state of charge). The measurement of the open-circuit voltage to determine the SoC is based on the relationship between the electromotive force and the concentration of the sulfuric acid in the battery.
- One of the major advantages with VRLA batteries is that they do not experience memory effect which is common with nickel cadmium batteries.

Disadvantages include:

- These batteries have a shorter life span than other types of lead-acid batteries. In UPS applications, a life span of 5–10 years is typical since their life reduces due to harsh operating conditions.
- They should not be stored in discharged condition.
- These batteries are sensitive to higher temperature environment. As with most batteries, the capacity is dependent on the discharge rate and temperature; the capacity decreasing with decreasing temperature and increasing discharge rate.
- Electrolytes act as heat sinks in batteries. However, VRLA batteries are “acid starved” as they use much less electrolyte, hence they do not have an effective heat-sink mechanism which makes them more prone to thermal runaway condition than compared to flooded lead-acid batteries.
- They have low cell resistance; hence immense short-circuit current is available.

Application Examples Because the VRLA batteries are sealed, they are ideal for many consumer applications. They are found in many uninterruptable power supply systems for computers, and as backup power for other electronics’ light security systems, and emergency lighting. Because high discharge rates are possible, they are also advantageous for engine starting.

Charging Characteristics Constant-voltage charging is the most efficient and fastest method of charging the VRLA battery. To carry out fast charging of VRLA battery, the charger must be capable of charging the battery at the 2C-rate. Fast charging is usually possible with a full charge achieved within 4 hours, and some batteries that accommodate even higher C-rates can charge so that they are returned to full capacity within

1 h. When float charging is used, the charger maintains each cell at 2.3–2.4V in order to ensure a complete charge and maximum battery life.

Nickel Cadmium (Ni-Cd)

General Characteristics Nickel-cadmium battery is a very reliable, sturdy, long-life battery. Little maintenance is needed on nickel-cadmium batteries. These batteries have two major variants based on the intended application. Cells with thin sintered plates have low internal resistance and have a high power to volume ratio, while cells with thick electrode plates have a high energy storage capacity. Nickel-cadmium batteries are manufactured as unsealed open/semi-open batteries in which electrolyte/gas can escape through a vent (vented Ni-Cd batteries) and as fully sealed batteries which do not require topping up of the electrolyte with water. Nickel-cadmium batteries exhibit voltage suppression, also called as memory effect. The memory effect causes the battery to deliver only the capacity, which was used during the repeated charge/discharge cycles before. Because of this, the whole capacity of Ni-Cd batteries should be used for each discharge cycle to avoid a decrease of the maximum capacity. “Memory effect” makes this battery less suited for applications that don’t allow a complete discharge.

Advantages and Disadvantages

Advantages include:

- They have a longer life than compared to lead-acid batteries.
- Extended operating temperature range compared to lead-acid batteries. This makes them more flexible in heavy duty applications in regard to temperature range.
- Extremely rugged batteries.
- Good charge retention. They can be stored for long periods without significant deterioration of SoC.
- These batteries require less maintenance.

Disadvantages include:

- Cadmium is an environmentally hazardous substance. Hence, disposal of Ni-Cd batteries is a major issue.
- They exhibit strong voltage depression (memory effect) phenomenon. This is a major drawback of Ni-Cd cells.

Application Examples Because of their favorable electrical properties, excellent reliability, low maintenance, rugged design, and long life, nickel-cadmium batteries are used in a large variety of applications. Unsealed Ni-Cd with higher capacity ranges are used in high-energy applications such as traction and large emergency power installations. Industrial nickel-cadmium batteries are used in train lighting and air conditioning for rail cars, emergency and standby systems such as emergency brakes and lighting in mass-transit and subway cars, diesel-engine cranking in locomotives and commuter cars, railroad signaling, communication along tracks, as well as standby power in rail stations and traffic control systems. The nickel-cadmium battery is also used in power-generating stations and power distribution. Sealed Ni-Cd batteries are usually of a low energy storage type (30 Ah). These are extensively used in consumer electronics, domestic markets, and low-energy applications.

Charging Characteristics Constant-voltage charging is the preferred method for unsealed nickel-cadmium batteries.

Nickel-Metal Hydride (Ni-MH)

General Characteristics Nickel-metal hydride (Ni-MH) cells share many of the same characteristics as nickel-cadmium cells and reduce some of the disadvantages. A major difference between nickel-metal hydride and nickel-cadmium cells is that cell reaction of nickel-metal hydride cells is exothermic, and hence, internal temperature of Ni-MH cell rises when it is in operation. On the other hand, nickel-cadmium cells have an endothermic cell reaction.

Advantages and Disadvantages

Advantages include:

- These batteries do not pose environmental hazards like Ni-Cd batteries.
- They possess higher specific energy and energy density than nickel-cadmium cells.
- Bipolar battery pack designs are popular as the energy storage in hybrid vehicles.

Disadvantages include:

- Overcharging leads to serious consequences for the battery; it leads to battery heating which in turn releases hydrogen gas and increases fire hazard. As a result, Ni-MH batteries require complex charging circuitry to ensure overcharging does not take place.
- Complex circuitry for charging implies Ni-MH cells cannot be charged on conventional battery chargers. This necessity contributes to an increased cost for Ni-MH battery.
- Limited service life of about 200–300 cycles if repeatedly discharged at high load currents.
- Higher self-discharge rate than Ni-Cd. Hence, the shelf-life of a fully-charged Ni-MH battery is much shorter. The shelf life is improved by adding chemical additives, which lowers the energy density.
- Memory effect is present but to a much lesser extent than Ni-Cd battery.

Application Examples The nickel-metal hydride battery used to be incorporated in computers, cellular phones, and other consumer electronic applications. In recent years, lithium-ion battery has replaced nickel-metal hydride batteries as it possesses a superior specific energy and energy density.

Charging Characteristics Repeated high load current discharging reduces the service life of nickel-metal hydride batteries to about 200–300 cycles. Ideal discharging of these batteries usually occurs at load currents of 0.2–0.5C. Ni-MH battery suffers from a high self-discharge rate. Self-discharge rates are reduced by adding chemical additives to the cell. However, this results in a trade-off, as chemical additives that slow down the self-discharge rate decrease the energy density of the cell. For a particular make of battery, it has been observed that it loses about 32% of charge if stored for about 80 h.

Lithium Ion (Li-Ion)

General Characteristics Lithium-ion cells are often specified for use in high-performance applications where small size and high performance are of paramount importance. They have higher specific energy and energy density than nickel-metal hydride cells.

High energy density of Li-ion cell also makes it less stable. These cells pose a potential fire hazard if not managed properly.

Advantages and Disadvantages**Advantages include:**

- Li-ion cells have a long cycle life (3,000 cycles at 80% depth of discharge). Hence, they are suited for applications which require a large number of charge-discharge cycles.
- They can operate over a wide temperature range.
- Low self-discharge rate leads to a long shelf life for these batteries.
- Rapid charge capability endears these batteries with consumer electronics applications.
- High energy efficiency. These cells can be up to 94% efficient in terms of energy over a cycle.
- No “memory effect.”
- These batteries do not pose an environmental hazard as they are not made up of toxic materials.
- High energy density (300–400 kWh/m³, 130 kWh/ton).
- One of the salient qualities of Li-ion cells is that they have a very high coulombic efficiency as compared to lead-acid cells. A new Li-ion cell exhibits up to 94% coulombic efficiency as against a lead-acid battery which has only 80% coulombic efficiency.

Disadvantages include:

- Li-ion cells have a moderately high initial cost.
- High energy density of Li-ion cells also gives rise to instability and fire hazard issues. This behavior of Li-ion cells makes it mandatory to have a complex protective circuitry. The battery management systems for Li-ion cell must be able to prevent overcharging of these cells. Overcharging in Li-ion cells leads to thermal runaway and subsequently a fire hazard.
- Venting and thermal runaway may take place when cells are crushed.
- Li-ion batteries composed of series strings of cells require charge equalization modules. Li-ion cells do not support low cost, easy to implement passive cell-balancing schemes.

Application Examples Li-ion batteries are employed in high-performance applications where size and energy are important. They are the preferred choice

for consumer electronics such as laptop computers, cellular telephones, and personal media player where long battery life is required. The suitability for use in military, aerospace, and automobile applications is also being explored.

Charging Characteristics Li-ion cells are fabricated in discharged state and thus must be charged before use. The cells are typically charged using either a constant current (CC) or a constant current-constant voltage (CCCV) with a taper charge regime. Exceeding the maximum voltage is a potential safety hazard and can result in irreversible damage to the battery. At the same time, charging to a lower voltage reduces the capacity of the battery. The construction of these batteries tends to make them susceptible to internal short circuits due to impurities. With the demand for higher energy density, an internal short can lead to catastrophic consequences including the risk of fire. Hence, internal temperature rise of the battery pack needs to be monitored as well as cell voltage. These considerations make it crucial to incorporate special control circuitry for lithium-ion batteries for management of charge and discharge. Although Li-ion cells have a flat voltage profile, it has been established in literature that cell open-circuit voltage provides a good estimate of the state of charge (SoC) ranging from 20% to 100%.

Sodium Sulfur (Na-S)

General Characteristics A sodium-sulfur battery is a type of molten metal battery constructed from sodium (Na) and sulfur (S). This battery has a high energy density, high efficiency of charge/discharge (89–92%), and long cycle life, and is fabricated from inexpensive materials. Sodium sulfur batteries usually have operating temperatures of 300–350°C. They are most prominently found in power grid operations, electric trains, and wind generation operations.

Advantages and Disadvantages

Advantages include:

- These batteries are constructed from inexpensive materials.
- Per unit volume, sodium sulfur batteries deliver three to five times more energy than lead-acid

batteries. They have a high specific energy in the range of 160 kW/h.

- Designed to last 15 years through 2,500 full charge/discharge cycles.
- It has up to 89% cell DC efficiency with no self-discharge.
- Insensitive to ambient temperatures which make it suitable to be housed outdoors.
- Extremely fast charge cycling; it can transit from full charge to full discharge in milliseconds.
- Sodium sulfur battery facilitates remote operation and monitoring along with the added benefit of minimum maintenance.

Disadvantages include:

- These batteries require an elaborate thermal management system to ensure energy efficiency.
- Cells need to be hermetically sealed when operated in corrosive outdoor environments.

Application Examples Sodium-sulfur batteries have operating temperatures of 300–350°C and extensively employ sodium polysulfides which are highly corrosive. These considerations make Na-S batteries suitable for large-scale nonmobile applications such as grid energy storage. Sodium-sulfur batteries have many applications in power systems. They are used to provide additional power during voltage sags. They provide prompt spinning reserves for grid frequency control and reactive power support. Sodium-sulfur batteries also perform admirably in stabilization of wind energy fluctuations by providing the necessary additional power. Na-S batteries are a possible energy storage technology to support renewable energy generation, specifically wind farms and solar generation plants. They are also a better option as against pumped hydroelectric storage schemes. In Europe, motivation is toward implementing Na-S batteries for automotive traction applications.

Lithium-Iron Monosulfide

General Characteristics Practical energy densities of 100 Wh/kg are achieved by secondary lithium-iron monosulfide cells. Lithium-iron sulfide batteries require a thermal management system to maintain optimum operating temperatures. Precise voltage monitoring is needed from the charger. This battery

system requires a thermal management system to maintain the rated operating temperature for the battery and a specialized charger in which careful voltage control is maintained. This battery technology was under active research in the 1970s for electric vehicles. It is yet to be commercialized.

Nickel Zinc (Alkaline Rechargeable System)

General Characteristics The nickel-zinc (zinc/nickel-oxide) battery is an alkaline rechargeable system. Currently the nickel-zinc system is capable of delivering about 50–60 Wh/kg and 80–120 Wh/L depending on the specific design. Nickel-zinc batteries are suited for high discharge rate applications such as a camera flash.

Advantages and Disadvantages

Advantages include:

- Good capacity retention has made it a competitor of silver-zinc and silver-cadmium systems. Fully charged nickel-zinc batteries lose about 20% of their original capacity within a month when left on open-circuit at 25°C. Nickel-zinc batteries can be stored for up to 3 years.
- It has a wide range of temperature tolerance (−39°C to +81°C operating temperature).
- One of the major plus points is that it has a flat discharge voltage profile for a significant portion of the discharge.
- Ni-Zn battery possesses a fast recharge capability.
- It has a sealed maintenance-free design.

Disadvantages include:

- The main stumbling block for the success of Ni-Zn battery technology is that Ni-Zn battery possesses a poor cycle life (up to 150 cycles).
- It has a relatively low volumetric energy density.

Application Examples Nickel-zinc provides a very low-cost option for a long-cycle-life alkaline-rechargeable system. The nickel-zinc system is suited for mobile applications such as electric bicycles, electric scooters, electric and hybrid vehicles, or other deep-cycle applications. Deep-cycle applications for nickel-zinc batteries include trolling motors, electric bicycles and scooters, wheelchairs, golf carts, electric

lawnmowers, electric vehicles, and similar uses. Nickel-zinc batteries have the required discharge-rate capability, high cycle life at deep depths-of-discharge, lightweight rugged construction, and are capable of being stored over the winter months without any maintenance charging.

Charging Characteristics The battery should be protected from excessive overcharge and over discharge. Extreme abuse may reduce battery performance and cycle life or cause a potential safety hazard.

Metal Air

General Characteristics The most popular metal-air battery is the zinc-air electrode battery. Zinc-air secondary batteries are being developed which can store three times as much as lithium-ion batteries but only cost half as much. The intended applications include cell phones, portable consumer electronic items, and electric vehicles. Lithium-air, calcium-air, and magnesium-air batteries have also been studied, but cost and problems such as anode polarization or instability, parasitic corrosion, nonuniform dissolution, safety, and practical handling have so far inhibited the development of commercial products.

Advantages and Disadvantages

Advantages include:

- Zinc-air battery has high energy density. Suitable for electric vehicle technologies.
- Zinc-air cells intake air with CO₂ removed. Earlier, this was seen as a disadvantage. However, deployment of this cell on electric vehicles with a CO₂ filter will lead to drastic reduction in CO₂ emissions. Hence, this cell is being proposed as a likely candidate for automotive applications.
- Zinc-air cells have a flat discharge voltage profile.
- These cells have a long shelf life (dry storage).
- Zinc-air battery has a safe battery chemistry which reduces fire hazards greatly.

Disadvantages include:

- Main difficulty in the development of rechargeable zinc-air battery is the deactivation in performance of air electrode after a few charge/discharge cycles.

- Internal short circuit is a major problem in Zn-Air secondary cells. Internal short circuit usually occurs after several charge/discharge cycles due to zinc dendrite growth through the separator.
- Depending on the discharge rate, the energy capacity of the cell drops drastically.
- Drying out of electrolyte limits shelf life once opened to air.
- Limited operating temperature range.

Application Examples Future applications for rechargeable zinc-air batteries include cell phones and electric vehicles. The high energy density, low-cost constituent materials, and relatively safe cell chemistry are some of the positive application advantages of this battery type. However, more efforts are required to increase the number of charge/discharge cycles of this battery before it becomes practical for commercial use.

Zinc-Bromine

General Characteristics The zinc-bromine battery is a high-energy-density battery. There are no toxic materials in this battery system. Zinc-bromine battery is constructed from low-cost materials; the battery cells are made up of plastic. It provides a viable energy storage option for a variety of generation sources and is ideally suited for applications requiring 2–10 h of energy storage. The energy density of this advanced battery makes it attractive for applications where traditional energy storage batteries, such as lead-acid batteries, are unacceptable due to size and weight restrictions. The zinc-bromine battery is a flow battery. Auxiliary systems are required for circulation and temperature control of the electrolyte. The zinc-bromine battery has a good shelf life. These batteries are more prominent in the high energy range: 10–500 kWh. These battery systems are custom built for specific applications.

Sodium-Beta

General Characteristics Sodium-beta batteries are high-temperature operating systems and hence have high energy density compared to ambient temperature systems.

Advantages and Disadvantages

Advantages include:

- Sodium-beta batteries are characterized by high energy density, lack of required maintenance, and performance independent of ambient temperature.
- They have a potential for low cost (relative to other advanced batteries) and are cheap as raw materials.

Disadvantages include:

- Thermal management is critical. Requires thermally insulated battery enclosure.
- These batteries operate in the region of 160–500°C. Hence, these batteries must not be affected by ambient temperatures.

Application Examples Sodium-beta battery technologies have been developed for use in relatively large-scale energy storage applications (10–1,000 kWh). Sodium-beta batteries can be used at generation facilities for load leveling, spinning reserve, and area regulation. They are also used for line stability and voltage-regulation purposes at distribution facilities. This technology is also suitable for peak demand reduction and power quality maintenance at a customer site. Sodium-beta batteries have also been investigated for their suitability in traction applications since, for a given physical envelope, sodium-beta batteries can provide significantly greater energy (range) at a reduced weight while meeting the vehicle power requirements compared with conventional battery technologies.

Battery Charging Circuits

Battery Charging Techniques

Proper battery charging techniques can significantly improve battery performance and life cycles. Thus, several factors such as fast charging, good quality of charging current, and avoiding under and over charging are considered. In particular, over charging can damage battery's physical components while under charging can reduce its energy capacity. Therefore, an appropriate control technique for charging process should be adopted. Different battery charging techniques are presented in this section. Operating principle of the battery charge controller is discussed for each technique, and the block diagram of the controller is depicted. Depending on the selected charging

technique, output voltage or current of the converter are fed back to the charge controller circuit. Each charging technique has a charging characteristic curve which is defined as the voltage-current trajectory of the battery during the charging period (v_{bat} versus i_{bat}).

Constant-Current Charging (CC) Constant-current charging is the most conventional battery charging technique. In the charging characteristic curve shown in Fig. 2a, the battery current is kept constant while battery voltage increases during charging until it reaches the maximum allowed value (i.e., rated voltage of the battery). Figure 2b shows the voltage and current profiles of the battery during the charging period. When the battery voltage has reached its final value, the charge controller circuit disconnects the battery from the converter to avoid overcharging and consequent battery failure. The voltage profile of the battery during the charging and discharging intervals is not necessarily linear, as shown in Fig. 2b, and depends on the type of the battery.

Figure 3 shows the associated control block diagram. The output current is compared with the reference current to produce the error current. The error current is fed to a proportional-integral (PI) controller to eliminate steady state error and generate the command signals for switching of the charger power electronic circuits.

The main advantage of this method is its simplicity. The converter circuit can be realized by an AC-DC or DC-DC converter based on the input type. Moreover, the output capacitor can be dropped as the output voltage regulation is not required, and

regulating merely the output current is sufficient. Elimination of the output capacitor simplifies the converter circuit to a first-order current filter which can be analyzed simply and implemented inexpensively. Fast charging can be realized by large current pumping; however, this has the potential to degrade the internal chemical reactions in the battery. Alternatively, the low charging current prolongs the charging time. Therefore, proper choice of the charging current is crucial for enhancing the charging performance and increasing the lifetime of the battery charging system.

Constant-Voltage Charging (CV) Constant-voltage charging is another conventional battery charging technique. The charging characteristic curve of this technique is illustrated in Fig. 4a. In this method, the battery voltage remains constant while the battery current is decreasing and eventually becomes very low. The current and voltage profile during charging is shown in Fig. 4b. This initial high current (I_o) temporarily increases the battery temperature and can degrade the battery, depending on the chemistry. The battery charge controller disconnects the battery from the charger circuit when the current reaches a specific amount (I_{min}), as shown in Fig. 4b. The control block diagram is shown in Fig. 3, where the sensed and reference variable is the battery and reference voltage, respectively.

Similar to the CC methodology, the CV charging strategy is straightforward and easy to implement. As opposed to the CC charging strategy, a capacitive output is required to regulate the output voltage. This

Batteries, Battery Management, and Battery Charging Technology. Figure 2

(a) Charging characteristic curve of the constant-current technique; (b) Current and voltage profiles of the battery during the charging process

Batteries, Battery Management, and Battery Charging Technology. Figure 3

Block diagram of the controller circuit useful for constant-current or voltage charging

Batteries, Battery Management, and Battery Charging Technology. Figure 4

(a) Charging characteristic curve of the constant-voltage technique; (b) Current and voltage profiles of the battery during the charging process

output stage increases the model order, and therefore, the controller design process is slightly more complex than CC technique, yet simple enough for low-cost applications.

The main disadvantage of the CV charging methodology is the temperature rise of the battery during initial charging stages. While the internal voltage of the battery is very low, the applied voltage at the terminal of the battery is relatively high. Thus, considering the small internal resistance of the battery, a large current will flow which can damage the battery. Another drawback of CV charging is the long charge time due to very low currents at the final stages of the charging.

Mixed Constant-Current and Constant-Voltage Charging (CC-CV) The CC-CV charging technique utilizes both CC and CV charging. Figure 5a, b illustrates the charging characteristic curve and current-voltage profiles of this method, respectively. The charging is performed in three stages. First, the battery current is kept constant until the battery voltage reaches a predetermined value (V_{const}). Then, the

battery voltage is kept constant while the battery current drops below a specific value (I_{min}). The final stage is the float charge stage where the battery voltage is reduced to compensate for the loss caused by self-discharge of the battery.

Since the current is kept constant at the first charging stage, the current rush disadvantage of CV charging technique is avoided. Also, since the voltage is kept constant at the second stage, the overcharging disadvantage of CC charging is avoided. Moreover, the float charging stage keeps the battery in full charge for a long time without degrading the battery. These advantages of CC-CV charging technique make it perfect for applications with high performance requirement. However, the design complexity makes this option more expensive compared to either CC or CV techniques.

Pulse Charging Pulse-charging technique is inherently a CC charging method that uses a pulsating charging current. This pulsating current causes the ions to distribute evenly throughout the battery and electrodes. Consequently, even distribution of ions

Batteries, Battery Management, and Battery Charging Technology. Figure 5

(a) Charging characteristic curve of the CC-CV technique; (b) Current and voltage profiles of the battery during the charging

prolongs the lifetime of the battery and enhances the charging performance. Figure 6 shows the current profile of the battery using pulse-charging technique. Due to the internal battery resistance, the battery voltage increases slightly during the charging subintervals. DC value of the charging current can be controlled by the duty cycle of applied current between zero and I_{max} . The charging rate is controlled by the DC value of charging current; thus, charging time of the battery can be controlled by the duty cycle:

$$t_{charge} = f(I_{DC}) = f(DI_{max}), \quad (1)$$

where D , I_{DC} , and I_{max} are the duty cycle, DC value, and the maximum of the battery current, respectively. Large duty cycles are applied during the initial stages of charging to ensure fast charging. After battery voltage is increased sufficiently, the duty cycle gradually decreases to prevent overcharging and consequent battery failure.

Pulse current charging needs an extra control loop to regulate the duty cycle of the reference current (I_{ref}) by the output voltage. As the output voltage decrease, this additional control loop decreases the duty cycle and consequently the DC value of the charging current. Following a pulsating reference current requires a fast control loop. The bandwidth of the control loop should be sufficiently higher than the switching frequency. This bandwidth is limited by the effective bandwidth of the current sensor. Thus, increasing the bandwidth of the controller requires high-bandwidth current sensors, which can be costly.

Taper Characteristic Charging In taper charging, neither battery current nor battery voltage is kept

Batteries, Battery Management, and Battery Charging Technology. Figure 6

Current profile of the battery using pulse-charging technique

constant. Instead, a linear combination of battery voltage and current is kept constant:

$$k_1 V_{bat} + k_2 I_{bat} = c = \text{constant}, \quad (2)$$

where k_1 and k_2 are constant coefficients which are determined by design requirements. CC and CV charging techniques are special cases of the taper characteristic charging in which $k_1 = 0$ or $k_2 = 0$, respectively. Figure 7a, b illustrates the charging characteristic curve and voltage-current profiles of the taper charging technique, respectively.

The block diagram of the charge controller using this technique is depicted in Fig. 8. Sensing of both battery voltage and current is required and is the main drawback of this strategy. Sensors are usually the most

Batteries, Battery Management, and Battery Charging Technology. Figure 7

(a) Charging characteristic curve of the taper-characteristic-charging technique; (b) Current and voltage profiles of the battery during the charging

Batteries, Battery Management, and Battery Charging Technology. Figure 8

Block diagram of the controller for taper characteristic charging

expensive components of the converter circuits, and increasing the number sensor may drastically increase the total cost of the system.

Assembled Characteristic Charging Assembled or modified charging is a technique whose characteristic curve is a combination of CC, CV, or taper characteristic curves. In this technique, when a certain threshold is reached (e.g., certain voltage), the characteristic curve is changed from one technique to another. Two conventionally assembled characteristic charging methods are assembled constant-current charging and assembled taper characteristic charging.

Assembled Constant-Current Charging Figure 9a illustrates the charging characteristic curve of the assembled constant-current charging technique. As seen in Fig. 9a, battery is charged by a high constant current (I_1) until the output voltage reaches the threshold voltage (V_{th}), after which the CC charging will continue using a lower constant current (I_2). Then, charging with low current will continue until the

output voltage reaches its maximum value (V_{max}), which is usually the rated voltage of the battery. The current and voltage profiles of the battery are shown in Fig. 9b.

As the high constant current reduces the charging time but increases the risk of overcharging, one may trade off between fast charging and overcharging protection. This drawback of CC charging has been overcome in assembled constant-current technique. Short charging time can be achieved by using high constant current (I_1) at the first stage ($v \leq V_{th}$), while overcharging can be avoided by using low constant current at the second stage ($v > V_{th}$).

Assembled Taper Characteristic Charging Assembled taper characteristic charging utilizes two different taper charging characteristic curves, as shown in Fig. 10a. The characteristic equation of this technique can be expressed as:

$$\begin{cases} k_1 V_{bat} + k_2 I_{bat} = c, & V_{bat} \leq V_{th} \\ k'_1 V_{bat} + k'_2 I_{bat} = c', & V_{bat} \geq V_{th} \end{cases} \quad (3)$$

where $c > c'$. Figure 10b depicts current and voltage profiles of the battery during the charging time interval.

Enhanced charging performance and prolonged battery life can be achieved using this technique. The main disadvantages of this technique are implementation complexity and using two sensors (current and voltage sensors).

Qualitative Comparison Between Different Charging Techniques Table 1 summarizes different charging techniques and their main properties:

Battery Charging Circuits for Photovoltaic (PV) Systems

Energy storage components are an essential part of a stand-alone photovoltaic (PV) system as they store energy during the high radiation hours during the day

and supply load during the low-radiation hours and nights. The battery is an effective energy storage technology for a PV systems. Lead-acid batteries are common due to their high energy density, prevalence and low cost. Different structures that can be used to connect the battery stack to the PV panel are presented in the next sections. In all of these structures, a series diode is connected between the PV panel and the battery to protect the battery against short circuit during the low-radiation conditions and nights.

Series Charge Regulators Figure 11 illustrates a typical charge regulator structure which can be used for both series and parallel charging. In series charging, switch S_2 is always open. Switch S_1 disconnects the PV panel from the battery when state of charge (SoC) of battery reaches 100% to protect the battery against overcharging. Switch S_3 disconnects the battery from

the load when the battery SoC is less than a predefined value to avoid deep discharging mode, which can degrade the battery and shorten its life. All switches should have very low loss which means they should have very low forward voltage and on-time resistance. Thus, mechanical relays are preferred to fast power semiconductors such as IGBTs with high on-time voltage drops.

Shunt Charge Regulators In a typical shunt charge regulator, the switch S_1 in Fig. 11 is always closed, and

switch S_3 operation is similar to series charge regulators to disconnect the load from the battery when battery SoC is less than a predefined value to prevent the battery from deep discharging. Switch S_2 shorts the output of the PV panel during low-radiation conditions and nights. When the output of the PV panel is shorted, series diode protects the battery against short circuit condition.

Pulse-Width Modulation Charge Regulators Superior charging functionality can be achieved using

pulse-width modulation (PWM) charge regulators. PWM-type charge regulators are able to eliminate external disturbances and can be programmed to follow a specific charging technique that has been discussed in section “[Battery Charging Techniques](#)”. [Figure 12](#) shows a buck-boost-type PWM charge controller with voltage and current feedback. The charge controller also has the ability to control switch S_2 to

disconnect the load under the condition in which battery SoC is less than a predefined value to protect the battery against deep discharging.

Battery Charging Circuits with AC Sources

Several factors should be considered when designing a charging circuitry with AC input voltage, e.g., nominal output DC voltage, allowable ripple in output current, type of the input AC voltage source (single-phase or three-phase), AC voltage source ratings (voltage and frequency), charger efficiency and power factor, charger current limiting capability, and recharge duration time. In this section, the conventional battery charger's configurations with an AC input source are discussed.

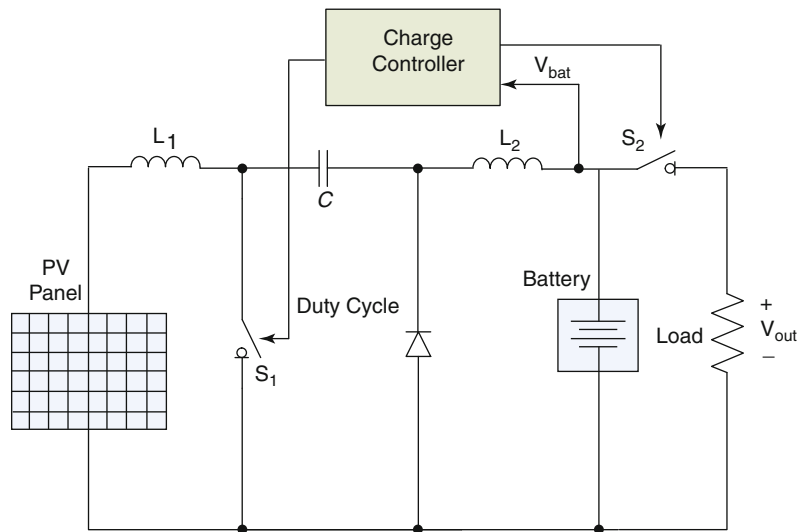

Battery Charger Configurations Given the DC nature of batteries, a rectifier circuit is needed. In a conventional configuration, shown in [Fig. 13](#), a phase-controlled rectifier is adopted. Another configuration is a rectifier bridge in series with a buck DC-DC converter as shown in [Fig. 14](#). If an electrical isolation is required, a DC-DC converter with a high-frequency isolation transformer can be used as shown in [Fig. 15](#).

Single-Phase, Phase-Controlled Rectifiers The circuit configuration of a single-phase thyristor-controlled rectifier is illustrated in [Fig. 16](#). The battery is presented as a DC voltage source in series with

a resistor (r_d). Considering a continuous battery current, the voltage and current waveforms are illustrated in Fig. 17. Due to the presence of AC side inductance, there is a commutation interval, u . In the continuous mode of battery's current, the approximate average value of the battery voltage is:

$$V_{\text{bat}} \approx 0.9 V_s \cos \alpha - \frac{2}{\pi} \omega L_s I_{\text{bat}, \min} \quad (4)$$

where $I_{\text{bat}, \min}$ is the minimum value of battery current which occurs at $t = \frac{\omega}{\alpha}$.

The average value of battery current can be calculated using (5):

$$V_{\text{bat}} = r_d I_{\text{bat}} + E_d. \quad (5)$$

Figure 18 shows the input line current (i_s). Neglecting L_s , AC source current is a square wave current with only odd harmonics. These harmonics can be expressed as (6):

$$I_{\text{sh}} = \frac{I_{s1}}{h} \quad (6)$$

where I_{s1} is the RMS value of the fundamental frequency of I_s . The total harmonic distortion of input line current in a single-phase configuration is around 48.43%. The power factor of the single-phase configuration is expressed in (7):

$$PF = 0.9 \cos \alpha. \quad (7)$$

At low values of i_{bat} , the battery current waveform may become discontinuous as shown in Fig. 19. Through the appropriate choice of firing angle α , one can control the average value of battery voltage and thus battery current and, therefore, the power delivered. Figure 20 shows the variations of V_{bat} versus i_{bat} for different values of α . For a given value of α , if i_{bat} becomes less than a specific threshold, V_{bat} increases sharply. In such a case, α has to increase to keep V_{bat} constant.

Three-Phase, Phase-Controlled Rectifiers Figure 21 shows the circuit configuration of a three-phase phase-controlled rectifier connected to a battery. Similar to the single-phase configuration, the battery is presented as a DC voltage source in series with a resistor (r_d).

Input line current

Batteries, Battery Management, and Battery Charging Technology. Figure 19
Battery voltage and current in discontinuous mode of operation

Batteries, Battery Management, and Battery Charging Technology. Figure 20
Rectifier output profile for different values of α

Assuming a continuous current for battery, battery's voltage waveform is illustrated in Fig. 22. In this figure, u and α present the commutation interval and delay angle, respectively. The average value of battery voltage can be expressed in terms of (8). Compared with the single-phase configuration, the ripple in the output voltage of three-phase rectifier is less:

$$V_{bat} \approx \frac{3\sqrt{2}}{\pi} V_{LL} \cos \alpha - \frac{3}{\pi} \omega L_S I_{bat} \quad (8)$$

where V_{LL} is the RMS value of the line voltage of AC source, and I_{bat} is the battery current.

Figure 23 shows the input line current of phase "a" (i_s). Neglecting L_S , AC source current harmonics can be expressed as (9):

$$I_{sh} = \frac{I_{s1}}{h} \quad \text{where } h = 6n \pm 1 \quad (9)$$

The total harmonic distortion of input line current in three-phase configuration is around 31.08%, less than that of a single-phase configuration. The power factor of three-phase configuration is:

$$PF = \frac{3}{\pi} \cos \alpha. \quad (10)$$

Rectifier Bridge in Cascade with a Buck DC-DC Converter In this configuration a rectifier is in cascade with a buck DC-DC converter. In the buck converter, which is shown in Fig. 24, the average output voltage is lower than DC input voltage. Figure 25 shows the waveforms of V_d , V_{bat} , V_L , and i_L for a resistive load and continuous conduction of inductor. t_{on} denotes the time that the switch is on in a switching period. Because of the fact that the integral of the inductor voltage should be zero over a time period, the output voltage is:

$$\frac{V_{bat}}{V_{in}} = \frac{t_{on}}{T_s} = D. \quad (11)$$

Ignoring losses, the expression for output current is:

$$\frac{I_{bat}}{I_{in}} = \frac{V_{in}}{V_{bat}} = \frac{1}{D}. \quad (12)$$

DC-DC Converter with a High Frequency Isolation Transformer In this configuration using a diode rectifier, the input AC voltage is rectified into a primary DC voltage. Using high-frequency switching, the primary DC voltage is converted from one DC level to another. This task is done by using a high-frequency transformer. The output of this configuration is controlled by adopting a PWM feedback control. Figure 26 shows the simplified block diagram of this configuration with its control system. Flyback, forward,

(a) Diode voltage; (b) Inductance voltage; (c) Inductance current

push-pull, half bridge, and full bridge are the main types of this battery configuration.

Flyback Converter Figure 27 shows the circuit topology of this converter. This converter is derived from buck-boost converter. Defining the switch duty ratio D as the ratio of the time the switch is on t_{on} to the total switching period T_s , $D = \frac{t_{on}}{T_s}$, the DC output voltage is:

$$\frac{V_{bat}}{V_{in}} = \frac{N_2}{N_1} \frac{D}{1-D}. \quad (13)$$

Forward Converter Figure 28 shows the circuit topology of this converter. This converter is derived

from a step-down (buck) converter. The expression for the DC output voltage level is:

$$\frac{V_{bat}}{V_{in}} = \frac{N_2}{N_1} D. \quad (14)$$

Push-Pull Converter Similar to forward converters, push-pull converters also have the same operation as buck converters. Circuit configuration of these converters is shown in Fig. 29. The expression for the DC output voltage level is:

$$\frac{V_{bat}}{V_{in}} = 2 \frac{N_2}{N_1} D, \quad 0 < D < 0.5. \quad (15)$$

In practice, in order to avoid simultaneous conduction of both switches, D should be less than 0.5.

Half-Bridge Converter Figure 30 shows the circuit configuration of this converter. This converter is also derived from step-down converters. The expression for the DC output voltage level is:

$$\frac{V_{bat}}{V_{in}} = \frac{N_2}{N_1} D, \quad 0 < D < 0.5. \quad (16)$$

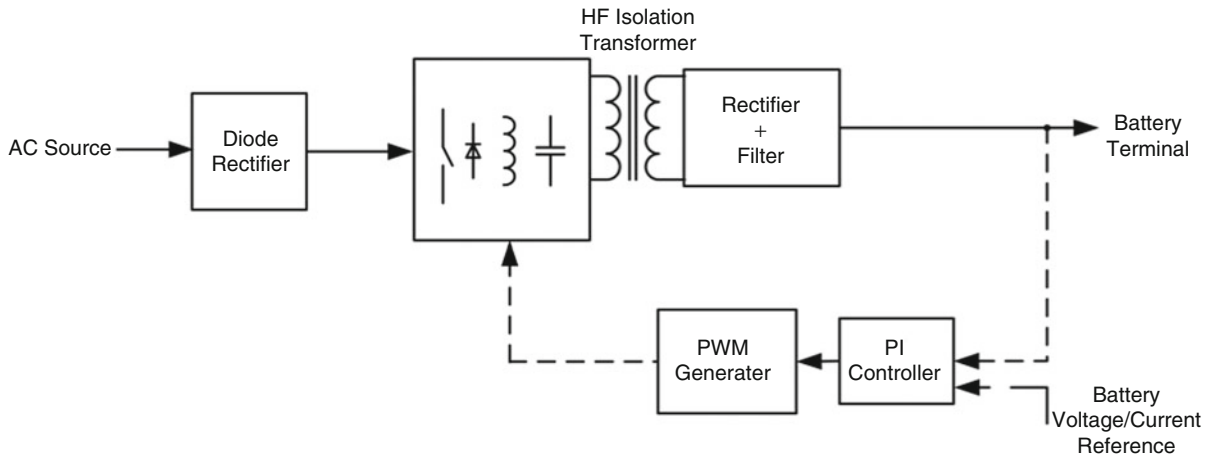

Full-Bridge Converter Full-bridge converters also have the same operation as buck converters. Their circuit configuration is shown in Fig. 31. The expression for the DC output voltage level is:

$$\frac{V_{bat}}{V_{in}} = 2 \frac{N_2}{N_1} D, \quad 0 < D < 0.5. \quad (17)$$

Bidirectional Configurations for Battery Charging with AC Sources

Bidirectional configurations for battery charging are used in multifunctional battery energy storage systems (BESS) and plug-in hybrid electric vehicles (PHEV). In the case of BESS, considering normal operation of the power system, the battery package can be charged and BESS can be controlled to shave the pick load. In the power failure condition, the battery pack is discharged and BESS provides an uninterruptible power for the utility grid. Figure 32 shows a three-phase configuration of a BESS system. Sophisticated control systems provide required commands for the switching system of the bidirectional converter which is a current-forced sinusoidal pulse-width modulated switching.

In the case of PHEVs, the battery pack should have this capability to store energy from an external power

source and regenerative braking as well as sending back the stored energy to the utility grid. Figure 33 shows the PHEV battery charger configuration. This battery charger consists of a bidirectional AC-DC converter in cascade with a bidirectional DC-DC converter.

Contactless Battery Charging

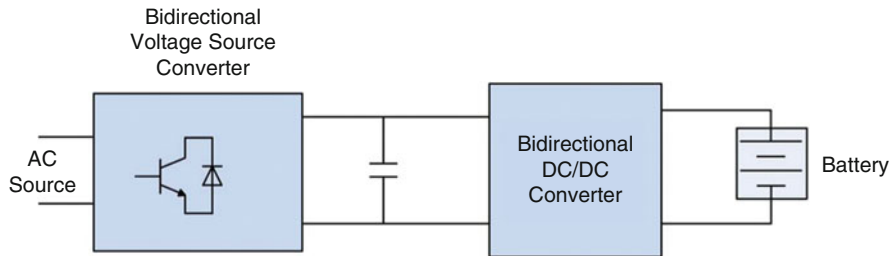

In recent years, a new approach for battery charging, named contactless battery charging, has emerged. This

new charging scheme alleviates the wiring requirements and provides an easy charging process for cell phones, laptops, cameras, PHEVs, etc. Currently, there are two dominant technologies for contactless battery charging named inductive contactless battery charging and capacitive contactless battery charging.

Inductive Contactless Battery Charging The planar contactless battery charging platform is the

Batteries, Battery Management, and Battery Charging Technology. Figure 32
Bidirectional configuration for BESS

Batteries, Battery Management, and Battery Charging Technology. Figure 33
Bidirectional configuration for PHEV

predominant technology for contactless chargers. It uses inductive interface between energy transmitter and energy receiver and has the potential to unify all battery charging protocols related to portable electronic devices such as cell phones, music players, etc. Generally, there are two main schemes for implementing inductive contactless battery charging. The first scheme adopts horizontal flux in which magnetic flux moves horizontally onto the planar charging surface and flows on both sides of the planar. To achieve this requirement, a thick layer of soft magnetic material such as ferrite or amorphous alloy as the flux guide is used. Figure 34a shows the charging platform with horizontal magnetic flux trajectories. Figure 34b shows the secondary harvesting device which should pick up the fluxes from the surface of the charging platform. This energy-harvesting device consists of a magnetic core and a winding and is mounted into the portable electronic device. The cross-sectional area of this device should be large enough to collect enough flux and energy.

The second scheme adopts perpendicular flux in which magnetic flux has a perpendicular trajectory

Batteries, Battery Management, and Battery Charging Technology. Figure 34

(a) Charging platform with horizontal magnetic flux trajectories; (b) Energy-harvesting device

flow to the charging platform surface. The magnetic flux has uniform magnitude over the charging platform. This perpendicular flux trajectory allows a slim energy harvester device which is mounted into the portable electronic device. Figure 35 shows the

charging platform with perpendicular magnetic flux trajectories.

Figure 36 shows the block diagram of an inductive contactless charger. The harvested energy is rectified, limited, and regulated to generate a DC voltage across the battery's terminals. Under and over discharge protection, setting of the battery voltage and current profiles, and implementing battery charging control techniques can be achieved by using an appropriate control system. Conventional configurations for battery charging circuits, explained before, can be used for the battery charger.

Capacitive Contactless Charger Thick electromagnetic flux guide is an important requirement in implementing efficient inductive contactless chargers. The confined electric field between conductive plates can alleviate this requirement in capacitive contactless chargers, as shown in Fig. 37. Figure 38 shows the circuit configuration of a capacitive contactless charger based on a series resonant architecture. Two coupling capacitors transfer power from V_{in} to battery. Considering a DC power supply, using an inverter, the input DC voltage is converted to an AC output voltage to enable current flow through the coupling capacitors. This inverter is not required if supplied from an AC

Batteries, Battery Management, and Battery Charging Technology. Figure 35
Charging platform with perpendicular magnetic flux trajectories

source. Inductors are used to enable soft switching. At the final stage, a diode rectifier provides the required DC voltage for battery charging. The circuit parameters should be designed in such a way that a circuit with the least possible value of capacitor and the desired efficiency is achieved.

Electromagnetic Interference (EMI)

Electromagnetic interference (EMI) is defined as degradation in performance of an electronic system caused by electromagnetic disturbances. Electromagnetic compatibility (EMC) is the ability of that system to operate satisfactorily in an electromagnetic environment without introducing intolerable electromagnetic disturbances to other devices in that environment. Battery charging circuits are power electronic converters in nature. Therefore, EMC rules and regulations exist that apply to the battery charger circuits. Power electronic converters must emit electromagnetic disturbances below the maximum permitted amount (emission) and be able to operate properly when exposed to electromagnetic disturbances below the maximum permitted amount (susceptibility).

Batteries, Battery Management, and Battery Charging Technology. Figure 37
Capacitive contactless power transferring

Batteries, Battery Management, and Battery Charging Technology. Figure 36
Inductive contactless charger scheme

Batteries, Battery Management, and Battery Charging Technology. Figure 38
Capacitive contactless charger circuit configuration

There are four types of electromagnetic disturbances: conductive noise, inductive coupling, capacitive coupling, and radiation.

Conductive Noise Conductive noise addresses disturbances introduced by coupling of two or more circuits through interconnecting wires. For example, when a utility transformer supplies a rectifier, it is exposed to the same current as of the rectifier. Therefore, if the input current of the rectifier has harmonic content that is intolerable for the transformer, it can cause the transformer to malfunction.

Inductive Coupling Inductive coupling refers to disturbances that are caused by unwanted coupling of windings in different circuits. Leaking flux of an inductor inside a circuit may encircle a winding or a closed path in another circuit and results in inductive coupling. Figure 39 illustrates the modeling circuit of inductive coupling. Mutual inductance, M , indicates the degree to which two circuits are coupled. The winding voltage set is denoted in (18):

$$\begin{cases} v_1 = L_1 \frac{di_1}{dt} + M \frac{di_2}{dt} \\ v_2 = M \frac{di_1}{dt} + L_2 \frac{di_2}{dt} \end{cases} \quad (18)$$

The noise is represented as a mutual term using the mutual inductance

$$v_{\text{noise},12} = M \frac{di_2}{dt}. \quad (19)$$

Capacitive Coupling Figure 40 portrays the capacitive coupling circuit. Capacitive coupling happens when there is a small capacitance between different parts of different circuits, and the medium is electric field. The disturbance voltage caused by V_g can be expressed as:

Batteries, Battery Management, and Battery Charging Technology. Figure 39
Modeling circuit of inductive coupling

Batteries, Battery Management, and Battery Charging Technology. Figure 40
Modeling circuit of capacitive coupling

$$V_{\text{noise}}(s) = \frac{Z(s)Cs}{Z(s)Cs + 1} V_g(s). \quad (20)$$

Thus, decreasing C reduces the magnitude of induced noise voltage.

Radiation Radiation disturbance is caused by the absorption of electromagnetic waves where it is not intended. When the circuit dimensions are very small compared to one fourth of the wavelength of an electromagnetic wave, that electromagnetic wave cannot be fully absorbed by the circuit. Thus, radiation disturbance usually occurs in high-frequency waves with shorter wavelengths.

EMC in Battery Charging Circuits

Different guidelines should be followed in battery charging circuits to reduce electromagnetic susceptibility and emission of the converter circuit. Radiation disturbance is trivial in power electronic converters because switching frequency is relatively low, which means that the wavelength of the electromagnetic wave is much longer than the circuit dimensions. Susceptibility of the converter to capacitive and inductive noises can be diminished by shielding the converter. Air core inductors should be avoided in the converter circuit to meet electromagnetic interference (EMI) and electromagnetic compatibility (EMC) emission requirements. Using air core inductors causes long flux paths through the air that can encircle other windings and cause inductive coupling. On the other hand, using magnetic core inductors defines a specific path for flux through the core and prevents inductive coupling. The most challenging EMC issue of the power electronic converters is conductive noises. As discussed in the previous sections, battery charging circuits are mainly AC-DC or DC-DC circuits. In DC-DC battery charging circuits, pulsating input current should be prevented to meet EMC emission requirements. Thus, buck and buck-boost converters are not suitable candidates. As an alternative, Boost, Ćuk, and SEPIC converters can be used as they have built-in input current filters. The most suitable choice is a Ćuk converter as it has output current filter that makes it perfect for constant-current charging applications. There are two types of AC-DC battery charging circuits, namely phase-controlled rectifiers and PWM rectifiers. Phase-controlled rectifiers draw square shape input currents that have a very high harmonic content. Thus, the designed input current filter for phase-controlled rectifiers should have lower cutoff frequencies which requires larger and bulkier filter components. On the

other hand, the input current of PWM rectifiers has less harmonic content that are located at higher frequencies. This characteristic of the PWM converters enables one to design input current filters by smaller inductors.

Regulations and Standards

Several standards have been developed by different institutes to regulate electromagnetic emission and susceptibility of electrical equipment, namely: MIL-STD 461; IEEE/ANSI SA-C63.14; IEEE 519, IEC 555-2, FCC, title 47, part 15; German VDE; and Japanese standards.

MIL-STD 461 establishes requirements for control of EMI emission and susceptibility of electronic and electromechanical equipment which are produced for use by agencies of the Department of Defense.

IEEE/ANSI SA-C63.14 provides the definitions for specific terms that are related to EMC, electromagnetic pulse (EMP), and electrostatic discharge (ESD).

IEEE-519 regulates the injection of harmonic currents to the power system due to nonlinear loads such as static power converters, arc discharge devices, saturated magnetic devices, and, to a lesser degree, rotating machines.

The IEC 555-2, IEC 1000-3-2, and IEC 1000-3-4 are emission standard related to operation of power electronic converter. These standards usually set an upper limit for harmonic content in each frequency.

Battery Management

Need for Battery Management

Two critical parameters for battery performance are battery voltage and operating temperature. A battery usually consists of a pack of cells connected in series. Manufacturing processes lead to imperfections in cells, as a result of which, all the cells in a pack are not identical. Electrical imbalances occur during charging and discharging of battery packs. Some cells in a battery will have different voltage levels for the same charging. This mismatch needs to be monitored to improve efficiency and safety of battery pack. Higher than rated temperatures in the batteries lead to undesirable chemical effects. Self-sustaining internal temperature buildup and gas pressure buildup are common. These conditions lead to safety hazards. It is vital to have a mechanism to monitor cell temperature and voltage and keep them within limits.

The main role of battery management systems (BMS) is to monitor cell voltage/current, state of charge/state of health, and the internal battery temperature and ambient temperature. The monitoring circuitry provides signals to the protection unit as well. Battery management systems differ on the basis of their primary functions, which depend upon the intended application. BMS for standby batteries in a power plant deal with monitoring of various battery parameters, maintaining readiness to deliver full power in the event of a system failure, and ensuring equal charging to increase battery life. On the other hand, a BMS in an electric vehicle must communicate with other controls in the automobile such as temperature controls, engine management, and safety systems.

There are three main objectives common to all battery management systems:

- Protect the cells or the battery from damage.
- Prolong battery life via smart control.
- Maintain battery in a state in which it can fulfill the functional requirements of the application for which it was specified.

State of Health Measurement

The state of health is a “measurement” that reflects the general condition of a battery and its ability to deliver the specified performance compared with a fresh battery. It takes into account such factors as charge acceptance, internal resistance, voltage, and self-discharge.

It is an estimate rather than a measurement. Battery manufacturers do not specify the SoH because they only supply new batteries. The SoH only applies to batteries after they have started their aging process either on the shelf or once they have entered service. The SoH definitions are therefore specified by test equipment manufacturers or by the user.

Any parameter which changes significantly with age, such as cell impedance or conductance, can be used as a basis for providing an indication of the SoH of the cell. Changes to these parameters will normally signify that other changes have occurred which may be of more importance to the user. These could be changes to the external battery performance such as the loss of rated capacity or increased temperature rise during operation, or internal changes such as corrosion.

Methods of Determining the State of Charge

State of charge (SoC) is defined as the capacity left in a battery expressed as a percentage of some reference. SoC of a battery is usually expressed as a percentage of the current battery capacity when it is fully charged. This definition may lead to an erroneous result when applied to a battery that has been in service for a long time. The maximum capacity of a battery reduces significantly with prolonged use. Considering this value to be the reference for state of charge measurement can lead to false results.

There are several techniques to determine SoC. A majority of them depend on measuring some convenient parameter which varies with the state of charge. Some are specific to particular cell chemistry. Some of the important ones are listed below:

Specific Gravity Measurement In lead-acid batteries, the electrolyte (sulfuric acid) is used up as the battery is subjected to a discharge cycle. As more and more electrolyte is used up, the specific density of sulfuric acid reduces. Thus, the specific gravity of the sulfuric acid is an indication of the state of charge for lead-acid batteries. This method is not feasible for VRLA batteries.

Voltage Measurement Cell voltage typically decreases for most cells during a discharge cycle. There is an almost linear relation between the state of charge and cell terminal voltage. Results may vary depending upon cell terminal voltage, temperature, discharge rate, and age of cell. A compensation factor needs to be included for SoC calculation by this method.

Li-ion cells have a flat voltage profile during a discharge cycle. The cell voltage drops abruptly when they are close to a complete discharge. As the cell voltage variation with SoC is not linear, cell voltage cannot be selected as a parameter to indicate SoC of Li-ion cells. In general, the voltage measurement technique fails for cells which have a flat voltage profile during a discharge cycle.

Current-Based SoC Estimation Charge in or out of the cell is calculated by integrating the current delivered by the cell for certain duration. This charge is

compared with the charge contained by a fully charged cell. This method provides a high accuracy for SoC measurement as it measures the charge directly. Three popular current sensing methods are used.

- **Current shunt:** The simplest method of determining discharge current is by measuring the voltage drop across a low ohmic value, high precision, series, sensing resistor. This resistor, connected between the battery and the load, is called a current shunt. This method of measuring current causes a slight power loss in the current path and also heats up the battery and is inaccurate for low currents.
- **Hall-effect transducers:** The Hall-effect transducers avoid the power loss problem, but they are more expensive. Unfortunately, they do not tolerate high currents and are susceptible to noise.
- **Giant magneto resistance (GMR) sensors:** These sensors are even more expensive than Hall-effect transducers, but they have higher sensitivity. They also have better high temperature stability than Hall-effect devices.

Kalman Filter Technique A Kalman filter is an algorithm to estimate the inner states of any dynamic system. The cell is represented by a mathematical state-space model, and SoC is considered as a state of the system. The Kalman filter accurately estimates the value of SoC and uncertainty. Armed with this information, the battery pack can be subjected to a more complete use, without fear of over- or under-charging cells. Nonlinear models of cells provide a highly accurate result.

The Kalman filter model for a rechargeable battery used in automobiles is initialized with a priori state estimate when the vehicle is turned on. The priori state estimate is provided on the basis of open-circuit voltage readings and a look-up table, self-discharge rate data from the cell model and the prior SoC when the vehicle was turned off. The algorithm then repeatedly updates the state estimate and state-uncertainty (error bound) estimate with each set of new measurements, as the system runs. Laboratory tests on real cells have shown that excellent SoC estimation with very tight error bounds are obtained whether or not the initial SoC estimate is accurate.

SoC Estimation from Internal Impedance Measurements During charge-discharge cycles, the composition of active chemicals changes in the battery, and this is reflected in the changes to internal impedance of the battery. Plots for variation of internal cell impedance with state of charge may be obtained for different cells. Thus, measuring internal impedance can indirectly provide information about SoC of the cell. However, on the flip side, cell internal impedance is also affected by temperature, which may lead to erroneous measurements.

Cell Balancing

When a battery pack is charged and discharged as a unit, individual cell temperature and internal chemistry characteristics can cause capacity imbalances in the form of voltage variations. Imbalances in cell voltages are caused by differences in cell capacities, internal resistances, chemical degradation, and inter-cell and ambient temperatures during charging and discharging. Any capacity imbalance between the modules can threaten the long-term reliability of the string as overall pack capacity is brought to the upper and lower limits of charge. Imbalances in cell voltages can cause cell overcharging and discharging, decreasing the total storage capacity and lifetime of the unit.

In a battery pack consisting of series connected cells, some cells have a diminished capacity owing to slight differences in manufacturing. When such a battery is subjected to charging cycle, the reduced capacity cells reach full charge earlier than the other cells in the battery, and there is a danger of overcharging these degraded cells. The capacity of the anomalous cells reduces even further with every successive charge/discharge cycle. The cumulative result is a temperature and pressure buildup which paves the way for an early failure of the cell.

Once a cell has failed, the entire battery must be replaced, and the consequences are extremely costly. Replacing individual failed cells does not solve the problem since the characteristics of a fresh cell would be quite different from the aged cells in the chain, and failure would soon occur once more. Some degree of refurbishment is possible by cannibalizing batteries of similar age and usage, but it can never achieve the level of cell matching and reliability that is possible with new cells.

Cell Charge Equalization

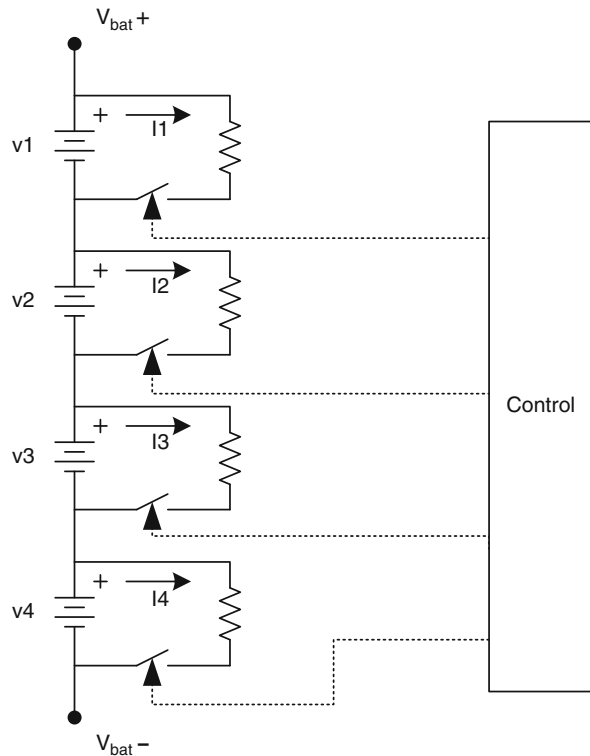

Battery management systems (BMS) for charge equalization monitor the state of charge of each cell. In low-cost applications, a circuit to monitor individual cell voltage may be employed. Switching circuits then control the charge applied to each individual cell in the series during the charging process to equalize the charge on all the cells in the pack.

A good charge/discharge equalization technique should ideally have the following features:

- High efficiency: Implementation of this technique should result in minimum power loss of the system.
- Small volume: Bulky volumes restrict portability and increase cost.
- Simple wiring schemes: Complex wiring schemes increase cost and decrease the reliability.
- In automobile applications, the cell must also be equipped to handle pulse charging from regenerative braking.

Passive Balancing Passive-charge balancing techniques involve bleeding off of charge from the cells with the highest voltage (hence, state of charge) in a battery pack (Fig. 41). A cell with a high charge is indicated by its higher cell voltage. Excess energy is removed through a bypass resistor until the voltage or charge matches the voltage on the weaker cells. Some passive balancing schemes stop charging the battery pack at the instant when any one of the cells in the pack reaches full charge. During discharge operation, they discharge the fully charged cells into a load until these cells reach the same charge level as the weaker cells. These schemes lead to underutilization of the battery pack.

Other schemes are designed to continue charging until all the cells are fully charged but to limit the voltage which can be applied to individual cells and to bypass the cells when this voltage has been reached. The shortcomings of this technique are that this method uses low bypass currents, and hence, equalization times are very long. Also, the battery pack performance is governed by the weakest cell. This process also causes power loss due to the bypass resistors which could drain the battery if operated continuously. It is however very easy to implement and is a low-cost

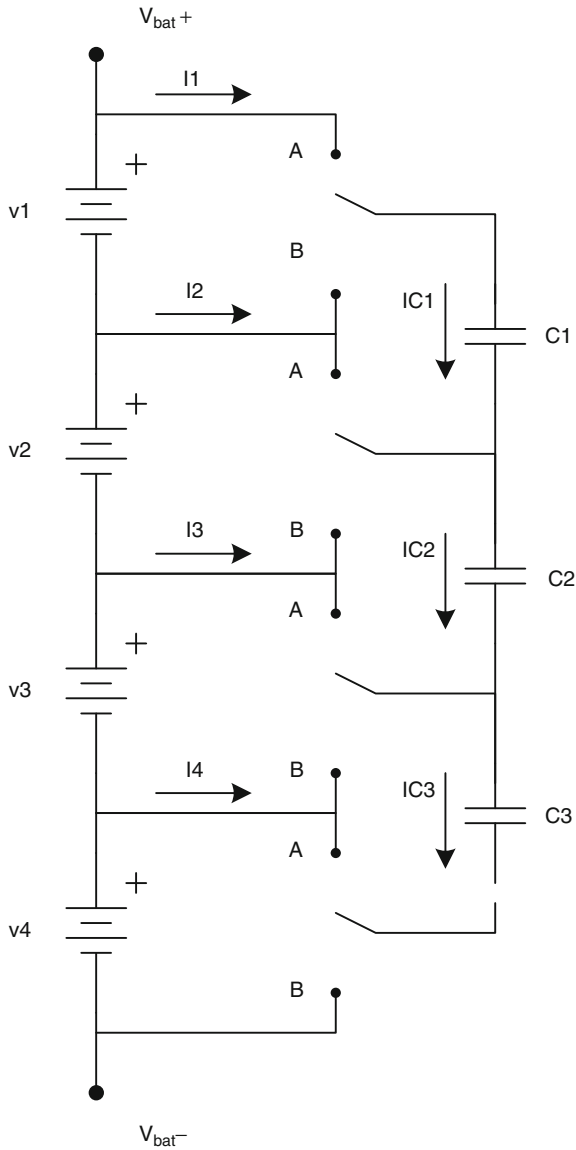

Batteries, Battery Management, and Battery Charging Technology. Figure 41

Passive charge balancing with a dissipative resistor

option. Passive balancing is adequate for both lead-acid and nickel-based batteries, incorporating series string up to about six cells. Passive equalization cannot be employed for charge equalization in Li-ion-based battery strings.

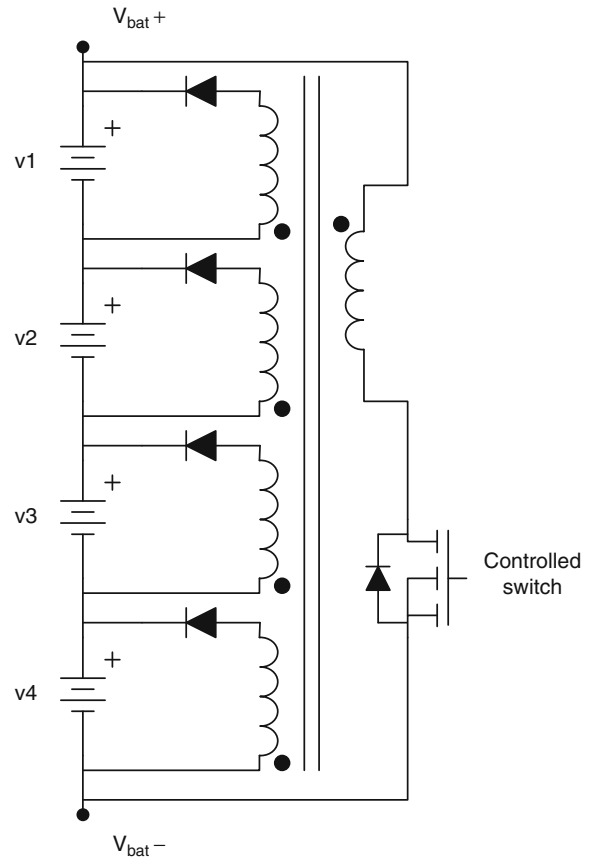

Switched Capacitor The switched capacitor charge equalization method, also called a flying capacitor method, uses a capacitor to transfer charge between cells in a battery pack. Typically, these are adjacent cells in the series string as shown in Fig. 42. When the capacitor is connected to a cell with the higher voltage, the capacitor is charged. When the charged capacitor is connected to a cell with a lower voltage, the capacitor discharges and transfers charge into the new cell. When switched between two cells repeatedly, this movement of charge results in current from the cell with higher voltage to the cell with lower voltage. Finally, cell voltages of all cells in the string reach the same value and voltage equalization is achieved. High-frequency

Batteries, Battery Management, and Battery Charging Technology. Figure 42

Schematic of a switched capacitor equalizer

switching can be accomplished using a single-pole double-throw switch implemented using two sets of MOSFETs. The MOSFETs are switched with frequencies ranging in several kHz. An important feature in the switching scheme is that switches break before make to prevent momentary short circuits of the respective cells. Accordingly, the switch control signals incorporate a dead-band interval. This method is easy to

Batteries, Battery Management, and Battery Charging Technology. Figure 43

A schematic of a flyback-type inductive shuttle charge distribution

implement and it results in reduced losses. A major drawback is that equalization process takes a long time if voltage differences between adjacent cells are small.

Multi-Output Transformer This method uses a transformer with its primary winding connected across the battery and one secondary winding which can be switched across individual cells. Both flyback and forward topologies are employed in practice. Figure 43 illustrates a flyback-based circuit to carry out charge balancing for a battery string. In the flyback structure, when the main switch is switched on, some energy is stored in the transformer magnetic field. When the switch is turned off, the energy is transferred to the secondary of the transformer, similar to the flyback concept. The bulk of the energy is taken up by

cells with lowest cell voltage. The main difference of this method over the switching capacitor scheme is that this method involves taking pulses of energy from the full battery, rather than small charge differences from a single cell, to top up remaining cells. Averaging of the charge level is similar to flying capacitor method, but it avoids the problem of small voltage differences in cell voltage and is consequently much faster. The transformer must have well-balanced secondary windings, otherwise voltage imbalances occur. Also, care must be taken to prevent transformer saturation.

DC-DC Converter Methods This technique involves using power electronics-based converters to transfer energy from higher charged cells to charge-efficient cells in a battery string. Different converter topologies such as the flyback, buck-boost, and Ćuk have been investigated to transfer energy between the batteries. Energy transfer may be unidirectional or bidirectional.

In unidirectional flyback mode, excess energy in the higher charged cell is transferred to the magnetized inductor of the transformer during turn-on operation of the converter. During the turn-off mode, this energy is returned to charge-deficient cells in the battery bank, and thus, charge leveling is achieved. Bidirectional converters are employed to facilitate local energy transfer between two neighboring cells independent of their respective cell voltage. The converters are operated in discontinuous mode to minimize switching losses. The disadvantage is that energy transmission efficiency is low when energy transfer occurs from the first cell to the last with many intermediate stages in a long string. To avoid power loss in intermediate stages, non-isolated buck-boost topologies have been explored in which energy is transferred from the first cell to all other cells in a bank without any intermediary.

Future Direction

Batteries and battery technologies are expected to become even more important in the future as consumers demand longer battery life from consumer electronics; variable energy sources, such as wind and solar, increase in prevalence in the electrical grid; and hybrid and all-electric vehicles become commonplace, to name a few applications currently driving technology development. The emphasis will be to develop

batteries with low cost, high energy density, low weight/volume, completely safe, environmentally friendly, easily disposable, and made from abundant raw materials. Auxiliary battery management systems will become increasingly integrated into the battery pack to create a true “plug and power” energy storage module.

Lithium-based cells hold great promise for the future. Lithium-ion cells have nearly proliferated the consumer electronics market. These batteries are also expected to find a prominent role as ideal electrochemical storage systems in renewable energy plants, as well as power systems for sustainable vehicles, such as hybrid and electric vehicles. However, scaling up the lithium battery technology for these applications is still problematic since issues such as safety, costs, wide operational temperature, and materials availability are yet to be adequately resolved. Safety is an important issue with Li-ion technology, and hence, it forms one of the most important aspects of future research. Lithium-copper cells are seen as the future prospect for lithium-based batteries, although the technology is still in a nascent state. Traditionally, cathodes of Li-based cells have not been reusable and hence the motivation for Li-Cu system which makes provision for reusable electrodes.

Li-air batteries in which oxygen from the air serves as the cathode and lithium as the anode are also being explored and hold promise to increase energy density. Estimates indicated that the lithium-air battery could hold 5–10 times as much energy as a lithium-ion battery of the same weight and double the energy for the same volume. In theory, the energy density could be comparable to that of liquid fuels such as gasoline. However, rechargeable Li-air batteries are still some years away. Flow batteries hold promise for stationary, high-energy applications such as power stations to provide peak loads, backup energy in case of emergencies, and source leveling to mitigate variable production from renewable sources. Zn-Bromine, metal air, vanadium redox are some of the batteries which are being explored for UPS and grid storage applications as an alternative to VRLA batteries, which is currently the standard.

On the battery management side, mobile energy platforms are driving push toward wireless charging technologies and standards for contactless charging.

The Wireless Power Consortium has recently developed the standard for contactless charging called “Qi” for low-powered electronic devices (i.e., less than 5 watts). This standard is suitable for cellular phones and contains interface definition, performance requirements, and compliance testing. Further progress is expected for more powerful chargers for higher-power-consumption devices such as laptops. In the future, all compatible devices with the “Qi” standard will carry the “Qi” logo to show compatibility with “Qi” transmitters. The final goal is to have portable electronic devices charged with the stations with “Qi” logo in airports, railway stations, hotels, etc. Currently, the inductive contactless chargers can transmit power in short distance and with the same speed as wired chargers (e.g., cell phone applications). However, capacitive battery chargers can transmit higher levels of power in shorter time frame. Once the associated costs are alleviated, capacitive contactless charges can dominate the market. It has already started in applications such as a camera flash, where the ability to transfer high power over a short period of time is important. Inductive contactless chargers, however, will remain prime candidates for vehicular-charging applications.

Intermittency of renewable energy systems introduces some integration problems especially for high penetration levels of wind and solar energy systems. The battery energy storage systems are expected to play an important role in addressing intermittency. Appropriate control strategies are under development for charging systems to make wind and solar plant hourly dispatched based on forecasted conditions. Bidirectional converters are a key element here; the battery is charged by the grid during low-demand hours or by wind and solar plants during high-irradiance hours and windy periods. The battery is then discharged to the grid during shading of solar panels or lower wind speeds.

Charging circuitry is also used in stations for electric and plug-in hybrid vehicles (EVs and PHEVs). Three standardized charging levels are defined by the National Electric Code for EVs and PHEVs. Level one method uses 120 V, 15 A (12 A usable) power outlets which are common in residential and commercial units in the USA. However, they prolong the charging period due to limited maximum power (about 1.44 kW). Level two chargers use 240 V, single-phase, 40 A, outlets.

They are known as the “primary” or “preferred” method of charging for PHEVs. There are two types of level two chargers, namely, inductive and conductive (wired). Although level two chargers enable faster charging, they require more safety restriction. Level three chargers use 480 V, 60–150 kW, three-phase power lines. They are intended to charge battery in about 10–15 min, also known as “fast charging” method. One may argue that PHEV batteries can be charged in 1–2 h using level two chargers, and thus, there are less incentives for higher power level three chargers in charging infrastructure for PHEVs.

Integrated battery chargers are an important aspect when considering system-on-chip devices. System-on-chip devices combine different parts of a system, which may conventionally require their own chip, into a single chip. For example, a typical system-on-chip sensor is designed to sense and transmit the data from an inaccessible location to the main controller. It is comprised of an integrated sensor, analog-to-digital converter, micro-controller, memory, and RF transmitter. Usually these system-on-chip sensors must be autonomous systems and thus generate their own power for an extended period of time. The required power for these micro-sensors can be supplied by solar cells or piezoelectric materials. Given the intermittency in the output of solar cell, micro-batteries are required to power the system during the low-light conditions. Therefore, integrated battery charging circuits are one of the essential components of system-on-chip sensors. Integrated battery chargers must meet specific criteria, namely, high efficiency, simple structure, and, most importantly, small size. Size is the prevalent factor in determining the total cost of the system in system-on-chip application. Therefore, in the applications that require extreme integration and low cost, battery is also integrated in the chip together with charger circuit.

Batteries, Introduction

RALPH J. BRODD

Broddarp of Nevada, Henderson, NV, USA

Batteries for storage of electricity from solar and wind generation farms are a key element in the success of sustainability. Electric vehicles are the second link in the chain powered by advanced battery systems. This section describes the various devices used in electrochemical energy storage including an overview of electrochemical processes and devices.

► **Nanocarbons for supercapacitors** describes electrochemical capacitors, sometimes called supercapacitors, and are energy storage devices similar to batteries but capable of delivering large amounts of energy in a very short time. These devices rely on the characteristics of the electrical double layer that forms on all conductors when immersed in an electrolyte. The electrical double layer has a high capacitance because the charges are separated on the order of atomic

dimensions. Since there is no mass transfer involved in the delivery of current, response time to a change is 10^{-6} s or faster. As a result, electrochemical capacitors can deliver large amounts of energy in short periods of time. The double layer forms in less than 10^{-6} s and responds to changes in a similar time frame. This is about 1,000 times faster than the electrochemical reaction at a battery electrode that has a time constant in the range of 10^{-3} s. The devices find application wherever power is required to service an application.

► **Electrochemical Supercapacitors and Hybrid Systems** describes electrochemical energy storage devices having higher energy density than electrolytic capacitors and higher power density than batteries. These devices rely on the characteristics of the electrical double layer that forms on all polarized conductors when immersed in an electrolyte. The double layer forms in less than 10^{-6} s and responds to changes in a similar time frame. This is about 1,000 times faster than an electrochemical reaction at a battery electrode that has a time constant in the range of 10^{-3} s. As a result, these can deliver large amounts of energy in a very short time. These devices find application where high power delivery is required.

► **Rechargeable Batteries, Separators for** describes the characteristics of porous membranes that hold the electrolyte and physically separate the negative from the positive electrodes in battery systems. The separator is a key element in battery construction as it physically separates and prevents direct contact (shorting) between the positive and negative electrodes. The separator materials are insulators but have the capability to absorb conducting electrolyte solutions to provide electrical continuity between the anode (negative terminal) and cathode (positive terminal) of the battery system. Each new battery system places new requirements placed on the separator material. The recent growth in the battery industry with the introduction of several new battery systems has resulted in the need to create and optimize new separator materials to meet the market demands. Correspondingly, the demand for novelty in separator membranes, to match the newer battery chemistries and geometries, continues to grow.

► **Lead Acid Battery Systems and Technology for Sustainable Energy** describes the basis for the many different commercial lead acid battery designs and electrical requirements ranging from automotive and

stationary energy storage to sustainable energy storage and power system regulation. The lead acid batteries constitute the single largest battery market segment. The reliability, availability, and low cost are the key to the success of the lead acid system. It is among the greenest of battery systems because of its established recycling industry. The ability to adapt the system to new applications and to optimize their performance to meet the demands of new applications has been a successful international effort for 150 years and continues to generate improved battery designs and power systems for the future.

While graphite is the material of choice for the anode in present commercial lithium ion batteries, an active search to identify a new high-energy anode material has identified ► [silicon-based anodes for Li-ion batteries](#) as a promising replacement for the graphite anode material. The silicon-lithium alloy has promise to significantly increase the cell capacity up to ten times that of the present graphite lithium anode. The successful transition will require developing method to handle the volume change characteristic of the silicon materials without disintegration of the anode structure. Strategies are based on fundamental mechanistic research to better understand the electrochemical lithiation and delithiation processes of silicon materials during charge-discharge cycling in terms of crystal structure, phase transitions, morphological changes, and reaction kinetics. It is expected that a viable silicon nanostructure anode can be developed with three to five times the capacity of graphite.

► [Nickel-based battery systems](#) describes the progression of higher-energy nickel cathode battery systems starting with iron for electric vehicle applications; followed by cadmium, metal hydride, hydrogen, and zinc anodes and their high power and good cycle life; and ending with nickel-hydrogen batteries for long life in space applications. At the turn of the twentieth century, simultaneously, Edison in the USA and Junger in Sweden independently developed the nickel-iron rechargeable battery system. The system powered the first electric vehicles in the early 1900s and is still produced today for long-life energy storage applications.

► [Lithium Ion Batteries, Electrochemical Reactions in](#) details the various advanced experimental techniques that are used to define the characteristics of new high performance materials as well as improve

the performance of existing materials for lithium ion batteries. X-ray, neutron and nuclear magnetic resonance techniques, etc. each provide essential complementary information on solid materials on the crystal structure of new and potential cathode and anode materials at an atom level leading to improved performance of existing materials as well as identifying potential high performance new materials.

► [Medical Device Batteries](#) describes wearable and implantable medical devices powered by batteries. Devices include those that are used for cardiac rhythm management (pacemakers, defibrillators, and heart failure devices), hearing loss, bone growth and fusion, drug delivery for therapy or pain relief, nerve stimulation for pain management, urinary incompetence and nervous system disorders, vision, diagnostic measurements and monitoring, and mechanical heart pumps.

► [Lithium-Ion Battery Systems and Technology](#) batteries have revolutionized battery powered electronic devices with its light weight, high energy storage capability, and long cycle life. Since its introduction in 1991, it has grown to a \$4+ billion market in 2010 and dominated powering the modern portable electronic devices. It replaced nickel cadmium and nickel metal hydride batteries and is positioned to power the electric vehicle market in the near future. The prime reasons for its rapid success and proliferation in consumer electronic market are high unit cell voltage, high energy density, and long cycle and shelf life with no memory effect. The significant progress of Li-ion batteries is mainly due to numerous innovations and advancements in materials, designs, and safety. This entry is intended to provide an overview of Li-ion batteries on several aspects. Starting with a brief discussion on its history, commercial success, and working mechanism, all the critical components inside the cell have been discussed with adequate details. The later part of this entry will primarily focus on manufacturing process with detailed discussion on cell-level safety, followed by overview of recent advances and modern trends in Li-ion systems.

► [Lithium-ion Batteries, safety](#) provides an overview of the safety considerations for Li-ion cells. Presently, Li-ion cells have a record of field failures or safety incident of one incident every ten million cells. The 18650 cell used in portable electronic applications contains sufficient energy to self-heat the cell to over

600°C. This does not include oxidation of the electrolyte solvent by the cathode oxide materials. Adiabatically, including the electrolyte, the temperature is significantly higher. The causes of an incident include overcharge and heating from external sources. All cells have safety devices such as PTC, CID, vents, and safety circuitry. An internal short is the most common trigger for a safety incident.

► **Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations** provide an example of the power of this experimental technique. Molecular orbital calculations have proven useful and have the capability to identify the details of lithium insertion into battery-related materials and to identify new cathode materials as well as improve the performance of existing materials. Crystallite size has tremendous effect to the thermodynamics and kinetics in intercalation compounds and impacts the diffusion/transport length, effective reaction surface area, surface energy, and interphase energy. Also, the experimental verification of one-dimensional lithium diffusion in Li_xFePO_4 was confirmed.

► **Battery cathodes** provides an overview of the current cathode materials available for use in Li-ion batteries and a discussion of the various battery systems. Li-ion batteries are dual intercalation systems, in which both the cathode and the anode have structures that allow reversible insertion and extraction of lithium cations. In principle, there are numerous materials that undergo reversible intercalation and can serve as electrode materials. Hence, unlike the lead acid battery which describes a specific chemistry, the chemistry of the Li-ion battery is not fixed but determined by the choice of anode and cathode materials.

► **Olivine Phosphate Cathode Materials, Reactivity and Reaction Mechanisms** provide a summary of the characteristics of the phosphate cathode materials. The interest in phosphates was triggered by the work of Goodenough in identifying lithium iron phosphate, LiFePO_4 , as a promising cathode material for use in Li-ion battery systems. The nanosize crystal structure gives the material unique properties including high surface area, very long cycle life, and, just as important, a low-cost cathode material.

The ► **Battery Components, Active Materials** for reviews the role played by the pioneers Volta, Daniell, Davy, Galvani, Faraday, and Davie in providing the

basis for batteries as they are known today. The key to identifying new battery materials is found in the fundamental properties of the materials and is the route to improve performance of present materials as well as the identification of new materials with long-life capability.

Anode – (negative electrode) This electrode donates electrons during cell discharge.

Battery A device consisting of one or many electrochemical cells connected together, in which chemical energy is converted into power. These can be further categorized as primary (non-rechargeable) or secondary (rechargeable) systems.

Capacity The amount of charge that a battery contains, often expressed as mAh or Ah. This depends on the size of the battery and its chemistry. Rated capacity also depends on the current used.

Cathode – (positive electrode) This electrode accepts electrons during cell discharge.

Cell One unit of a battery, commonly consisting of an anode, a cathode, an electrolyte, a separator, and two current collectors.

Energy density or specific energy Energy per unit volume or weight of a material or a device, respectively, often expressed as Wh/L or Wh/kg. Energy is

a product of the cell voltage and capacity per unit volume or weight.

Intercalation compound (host material, insertion compound) Originally, this referred specifically to layered structures that can undergo insertion of ions or molecules between the van der Waals gaps, but is now commonly used for any structure that undergoes topotactic insertion reactions. For Li-ion battery materials, it refers specifically to compounds that undergo reductive insertion of lithium ions, such as graphite (used as an anode) or LiCoO_2 (used as a cathode).

Jahn–Teller effect The geometric distortion of nonlinear complexes of certain transition metal ions to remove degeneracy. For example, Mn(III) in octahedral coordination is expected to have an electronic configuration of $t_{2g}^3 e_g^1$. Elongation along one axis of the octahedron, for example, decreases the symmetry and removes the degeneracy.

Power density and specific power Power per unit volume or weight, respectively, often expressed as W/L or W/kg. Power is the product of the current and the operating voltage. This is a function both of the materials used and the cell design.

Practical energy density or specific energy Based on the entire weight or volume of the device including inert components. It may be only 1/4–1/2 of the theoretical energy density. It may also refer only to the useable portion of the theoretical capacity of the anode or cathode material itself.

Ragone plot A plot showing the relationship between energy density and power density for any particular battery chemistry. This relationship is a function both of battery design and chemistry for Li-ion batteries.

Solid electrolyte interface (SEI) A very thin (nanometer scale) layer formed on a lithium or lithiated graphite anode, which develops upon reaction with certain kinds of electrolytic solutions. The SEI is a specific kind of reaction layer that is ionically conductive but electronically insulating. It passivates the electrode, preventing further reaction with the electrolytic solution, and allows reversible operation of the device.

Specific capacity The amount of charge per unit weight that a battery electrode material contains, often expressed as mAh/g. This is a fundamental

characteristic of the material, and depends upon its redox chemistry and structure.

Theoretical energy density, specific energy, capacity Based on weight or volume of the electrode active materials only.

Topotactic transformation A transformation in a crystal lattice involving displacement or exchange of atoms, which maintains the basic structure.

Definition of the Subject and Its Importance

In a discharging battery, the cathode is the positive electrode, at which electrochemical reduction takes place. As current flows, electrons from the circuit and cations from the electrolytic solution in the device move toward the cathode. Although these processes are reversed during cell charge in secondary batteries, the positive electrode in these systems is still commonly, if somewhat inaccurately, referred to as the cathode, and the negative as the anode. Because this terminology is widespread throughout the Li-ion battery literature, this usage will be adopted for this article.

Li-ion batteries are dual intercalation systems, in which both the cathode and the anode have structures that allow reversible insertion and extraction of lithium cations. In principle, there are numerous materials that undergo reversible intercalation and can serve as electrode materials. Hence the chemistry of the Li-ion battery is not fixed, unlike the great majority of battery systems. The choice of cathode greatly affects the performance and cost of a Li-ion battery; for example, it is a major determinant of energy density, since it typically has a lower specific capacity than the most common anode material, graphite (372 mAh/g), to which it must be matched.

Introduction

The very high theoretical capacity of lithium (3,829 mAh/g) provided a compelling rationale from the 1970s onward for the development of rechargeable batteries employing the elemental metal as an anode. The realization that some transition metal compounds undergo reductive lithium intercalation reactions reversibly allowed the use of these materials as cathodes in these devices, most notably, TiS_2 [1–3]. Another intercalation compound, LiCoO_2 , was described shortly thereafter [4, 5] but, because it was produced

in the discharged state, was not considered to be of interest by battery companies at the time.

Due to difficulties with the rechargeability of lithium and related safety concerns, however, alternative anodes were sought. The graphite intercalation compound (GIC) LiC_6 was considered an attractive candidate [6] but the high reactivity with commonly used electrolytic solutions containing organic solvents was recognized as a significant impediment to its use. The development of electrolytes that allowed the formation of a solid electrolyte interface (SEI) on surfaces of the carbon particles was a breakthrough that enabled commercialization of Li-ion batteries [7]. In 1990, Sony announced the first commercial batteries based on a dual Li-ion intercalation system [8]. These devices are assembled in the discharged state, so that it is convenient to employ a prelithiated cathode such as LiCoO_2 with the commonly used graphite anode. After charging, the batteries are ready to power devices.

The practical realization of high energy density Li-ion batteries revolutionized the portable electronics industry, as evidenced by the widespread market penetration of mobile phones, laptop computers, digital music players, and other lightweight devices, since the early 1990s. In 2009, worldwide sales of Li-ion batteries

for these applications alone were US\$7 billion [9]. Furthermore, their performance characteristics (Fig. 1) make them attractive for traction applications such as hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs), and electric vehicles (EVs); a market predicted to be potentially ten times greater than that of consumer electronics. In fact, only Li-ion batteries can meet the requirements for PHEVs as set by the US Advanced Battery Consortium (USABC), although they still fall slightly short of EV goals.

In the case of Li-ion batteries, the trade-off between power and energy shown in Fig. 1 is a function both of device design and the electrode materials that are used. Thus, a high-power battery (e.g., one intended for an HEV) will not necessarily contain the same electrode materials as one designed for high energy (i.e., for an EV). As is shown in Fig. 1, power translates into acceleration, and energy into range, or miles traveled, for vehicular uses. Furthermore, performance, cost, and abuse-tolerance requirements for traction batteries [11] differ considerably from those for consumer electronics batteries. Vehicular applications are particularly sensitive to cost; currently, Li-ion batteries are priced at about US \$1,000/kWh, whereas the USABC goal is US \$150/kWh [12]. The three most

Battery Cathodes. Figure 1

expensive components of a Li-ion battery, no matter what the configuration, are the cathode, the separator, and the electrolyte [13]. Reduction of cost has been one of the primary driving forces for the investigation of new cathode materials to replace expensive LiCoO_2 , particularly for vehicular applications. Another extremely important factor is safety under abuse conditions such as overcharge. This is particularly relevant for the large battery packs intended for vehicular uses, which are designed with multiple cells wired in series arrays. Premature failure of one cell in a string may cause others to go into overcharge during the passage of current. These considerations have led to the development of several different types of cathode materials, as will be covered in the next section. Because there is not yet one ideal material that can meet requirements for all applications, research into cathodes for Li-ion batteries is, as of this writing, a very active field.

Characteristics of Battery Cathode Materials

Modern cathode materials for Li-ion batteries are generally prepared in the lithiated (discharged) state, so that they can be paired with delithiated anodes such as graphite. For ease of handling, it is desirable that the material be reasonably air-stable at room temperature. Furthermore, graphite anodes impose a penalty of approximately 0.1 V in average cell potential compared to Li metal. To compensate for this, and also to maximize energy density, cathodes intended for use in

Li-ion batteries have higher average potentials versus Li/Li^+ than earlier materials such as TiS_2 and vanadates [14] developed for Li metal batteries. Furthermore, the requirement for high specific capacity generally restricts choices to compounds containing first-row transition metals (usually Mn, Fe, Co, and Ni). Environmental and toxicity concerns have precluded the development of most V or Cr-containing materials, although electroactive compounds containing these metals exist. Today's technologically important cathodes fall into two broad categories: metal oxides and polyanionic compounds.

Figure 2 shows representations of the crystal structures of the most commonly used cathode materials for Li-ion batteries, and Table 1 summarizes their general properties. Figure 3 shows typical discharge profiles of selected materials in Li half-cell configurations.

Layered Transition Metal Oxides

LiCoO_2 was the first of the layered transition metal oxides to be commercialized, and is still used today in batteries for consumer devices. It has the structure shown in Fig. 2a, where Co and Li, located in octahedral sites, occupy alternating layers along the 111 planes in a cubic close-packed (ccp) oxygen array, to form a structure with overall hexagonal symmetry (space group $R\bar{3}m$). This type of stacking arrangement is called O3 in layer notation, indicating that there are three transition metal layers per unit cell and the Li ions are octahedrally coordinated.

Battery Cathodes. Figure 2

Structures of common cathode materials: (a) The layered structure of LiCoO_2 with c -axis oriented vertically. The octahedrally coordinated Li ions in $3a$ sites are represented as spheres and CoO_6 (Co in $3b$ sites) as octahedra; (b) the cubic structure of LiMn_2O_4 spinel, with tetrahedrally coordinated Li ions (in $8a$ sites) represented as spheres, and MnO_6 (Mn in $16d$ sites) as octahedra; and (c) the olivine structure of LiFePO_4 , looking down the b -axis. Octahedrally coordinated Li ions are represented as spheres, and FeO_6 and PO_4 as octahedra and tetrahedra, respectively

Battery Cathodes. Table 1 Characteristics of commercial Li-ion battery cathode materials

Material	Structure	Potential versus Li/Li ⁺ , average V	Specific capacity, mAh/g	Specific energy, Wh/kg
LiCoO ₂	Layered	3.9	140	546
LiNi _{0.8} Co _{0.15} Al _{0.05} O ₂ (NCA)	Layered	3.8	180–200	680–760
LiNi _{1/3} Co _{1/3} Mn _{1/3} O ₂ (NMC)	Layered	3.8	160–170	610–650
LiMn ₂ O ₄ and variants (LMO)	Spinel	4.1	100–120	410–492
LiFePO ₄ (LFP)	Olivine	3.45	150–170	518–587

**Battery Cathodes. Figure 3**

Discharge profiles of lithium cells containing LiFePO₄, Li_{1+x}Mn_{2-x}O₄, or LiNi_{1/3}Co_{1/3}Mn_{1/3}O₂ electrodes

Delithiation proceeds topotactically [15, 16] and is reversible over the composition range $1 \geq x \geq \sim 0.5$ for x in Li_xCoO₂, giving a practical specific capacity of about 140 mAh/g below 4.2 V versus Li/Li⁺. Extraction of lithium to values of $x < \sim 0.5$ results in higher practical capacities initially, but often increases cycling losses [17]. This has been attributed to side reactions involving particle surfaces, which increase cell impedance, and to structural instability associated with phase changes at very low values of x in Li_xCoO₂ [18–21]. Coating LiCoO₂ particles, or rigorous heat treatment to remove surface species [22–24], results in improved cycling below 4.5 V versus Li/Li⁺, but full delithiation is still not possible without cycling losses.

A layered compound with the nominal composition of LiNiO₂ has also been extensively studied for battery applications [25–28]. Its lower cost compared to LiCoO₂, and the potential for higher energy density were driving forces for its development. Although the structure is similar to LiCoO₂, LiNiO₂ readily exhibits non-stoichiometry. During synthesis, there is a tendency toward loss of lithium and reduction of some Ni to the +2 oxidation state. The Ni²⁺ migrates to Li⁺ 3a sites, due to the similarities in size between the two types of ions. The actual composition can be written as Li_{1-z}Ni_{1+z}O₂ with $0 < z < 0.2$, or as (Li_{1-z}Ni_z²⁺)_{3a}(Ni_z²⁺Ni_{1-z}³⁺)_{3b}O₂ [29]. The degree of disorder is influenced by the synthetic conditions, and the electrochemical properties (e.g., the first cycle reversibility) are affected by the degree of non-stoichiometry [30, 31]. The difficulty in synthesizing high-quality LiNiO₂ was one impediment to its widespread adoption as a cathode material in Li-ion batteries, although nearly ideal structures can be obtained if sufficient care is taken [29]. (However, perfectly stoichiometric LiNiO₂ materials probably do not exist). Partial substitution of Ni with Co [32] was later found to be effective at reducing the cationic disorder on 3a sites, leading to compositions such as LiNi_{0.8}Co_{0.2}O₂. Cobalt also helps to reduce oxygen loss at high states-of-charge, improving safety.

The thermal instability of Li_xNiO₂ at high states-of-charge [33–36] also raised a great deal of concern about the safety of this material when used as a cathode. The properties of LiNiO₂ have been improved via coating and doping with Mg, leading to a very high-capacity electrode material [37] with better thermal properties. However, the most commonly

used electrode material related to LiNiO_2 is $\text{LiNi}_{0.8}\text{Co}_{0.15}\text{Al}_{0.05}\text{O}_2$ or NCA, which is now commercially produced (see Table 1 for general properties). The presence of Al in NCA improves both the thermal [33–36] and electrochemical properties [38, 39]. The high specific capacity and good power capability of this material make it attractive for vehicular applications although it is still not considered as inherently safe as other candidates such as LFP (see Table 2 and the discussion of olivines below).

Battery Cathodes. Table 2 Relative merits of selected commercial Li-ion battery cathodes

Advantages	Disadvantages
LMO (LiMn_2O_4 and variants)	
Low cost Excellent high rate performance High operating voltage No resource limitations Moderate safety (oxygen release)	Mn solubility issue, affecting cycle life Low capacity
LFP (LiFePO_4 and variants)	
Moderately low cost Excellent high rate performance No resource limitations Very slow reaction with electrolyte Excellent safety (no oxygen release)	Low operating voltage Low capacity, especially for substituted variants Controlling patents
NMC ($\text{LiNi}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}\text{O}_2$) and variants	
High capacity High operating voltage Slow reaction with electrolytes Moderate safety (oxygen release)	High cost of Ni and Co Potential resource limitations Relatively new in performance Controlling patents
NCA ($\text{LiNi}_{0.8}\text{Co}_{0.15}\text{Al}_{0.05}\text{O}_2$)	
Performance is well established Slow reaction with electrolytes High capacity High voltage Excellent high rate performance	High cost of Ni and Co Potential resource limitations Controlling soft patents

Several ternary Li-Fe-O phases exist with differing arrangements of cations in cubic close-packed oxygen arrays [40]. However, LiFeO_2 with the R-3m structure is metastable and generally must be prepared via indirect methods such as ion exchange of NaFeO_2 . The electrochemical properties of this material [41] and most other polymorphs [42, 43] are not, however, suitable for lithium-ion batteries due to low and highly sloping voltage profiles or poor cycling properties. Li_5FeO_4 with the anti-fluorite structure has a potential profile that may be compatible in a Li-ion battery configuration, but delithiation does not appear to proceed via simple oxidative deintercalation [44]. This material has been proposed for use as a lithium-ion source for lithium-ion batteries (i.e., to lithiate graphite anodes so that cathodes in the charged state may be used).

Ternary Li-Mn-O phases with Mn in the +3 or +4 oxidation state crystallize as spinels, the rock salt structure Li_2MnO_3 , or as orthorhombic LiMnO_2 with a corrugated structure (o- LiMnO_2) but not as O3 layered structures. Lithium manganese oxide spinels (LMO) are technologically important cathodes and will be considered in a later section (*vide infra*). The Na-Mn-O system contains numerous polymorphs, including layered structures. NaMnO_2 has the same stacking arrangement as LiCoO_2 , but is monoclinically distorted (space group C2/m), due to the abundance of Jahn–Teller distorted Mn^{3+} ions. Ion exchange of this compound yields a layered LiMnO_2 (designated O'3, with the prime indicating the monoclinic distortion) [45], but it rapidly converts to spinel upon electrochemical cycling, as does orthorhombic LiMnO_2 [46]. O'3- LiMnO_2 , o- LiMnO_2 , and spinel manganese oxide all have cubic close-packed oxygen arrays and differ only in the cation arrangement. Upon electrochemical delithiation of the first two materials, disproportion of Mn^{3+} into Mn^{2+} and Mn^{4+} ions occurs and Mn^{2+} ions subsequently migrate into vacant sites in the lithium layers via low-energy pathways, facilitating structural rearrangement to spinel [47].

Lithium-deficient layered $\text{Li}_x\text{MnO}_{2+y}$ ($x \approx 0.7$, $y \geq 0.05$), which has an O2 rather than O3 stacking arrangement, does not convert to spinel upon cycling [48, 49], because the oxygen array is not ccp. In addition, non-stoichiometric lithium manganese oxides that are intergrowths of O2 and O3 phases show better

resistance to conversion than the pure O3 structure [50, 51]. The presence of transition metal vacancies in these compounds (which reduce the concentration of the Jahn–Teller Mn^{3+} ions) results in low rate capability, because the vacancies tend to trap nearby lithium ions, impeding their mobility [52].

Other lithium manganese oxides with tunnel structures [53–55] exhibit interesting electrochemical properties, particularly those based on the $\text{Na}_{0.44}\text{MnO}_2$ structure. This material has excellent cycling characteristics [56] and rate capability [57], and does not convert to spinel, although the practical capacity is limited by voltage considerations (the average potential at which lithium is extracted is the highest of any known manganese oxide [58]). All of these tunnel and O2 or O2/O3 layered materials, however, must be prepared via ion exchange of their sodium manganese oxide structural analogs, complicating their preparation. Furthermore, the lithium deficiency of the ion-exchanged materials limits the capacity in Li-ion battery configurations, as all of the cycleable lithium must originate from the cathode.

Li_2MnO_3 can be considered a layered structure similar to LiCoO_2 , but with 111 planes alternately occupied by Li and $\text{Li}_{1/3}\text{Mn}_{2/3}$. Ordering of Li and Mn in the transition metal layer imposes a monoclinic superstructure, but the stacking arrangement is essentially identical to that of the R-3m structures discussed above. Mn in this compound is tetravalent and all lithium sites are occupied, precluding either oxidative deintercalation or reductive intercalation. Nevertheless, several researchers have observed electrochemical activity of Li_2MnO_3 when it is charged in lithium half-cells to high potentials [59]. Recent evidence [60] suggests that lithium deintercalation occurs with simultaneous oxygen loss during the initial charge, as well as H^+/Li^+ exchange. The converted material becomes electroactive and can subsequently be lithiated during cell discharge. Acid leaching of Li_2MnO_3 also yields an electroactive manganese oxide phase [61]. The reaction involves loss of Li_2O from the structure and ion exchange, to produce layered $\text{H}_{1-x}\text{Li}_x[\text{Li}_{0.33}\text{Mn}_{0.67}]\text{O}_2$ [62].

The compound $\text{Li}_{1.2}\text{Mn}_{0.4}\text{Cr}_{0.4}\text{O}_2$ [63] is essentially a solid solution of layered Li_2MnO_3 and LiCrO_2 with an O3 stacking arrangement [64]. Very high discharge capacities (~ 200 mAh/g) can be obtained based on

$\text{Cr}^{3+} \leftrightarrow \text{Cr}^{6+}$ redox processes. Conversion to spinel phases does not occur because Mn remains in the +4 oxidation state throughout charge and discharge, nor does the electrode need chemical or electrochemical activation prior to use. Nevertheless, concerns over the environmental impact of hexavalent chromium have prevented further development of this material.

The search for improved layered oxide materials containing low-cost transition metals ultimately led to the discovery of $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ [65–67] as well as compounds with the general composition $\text{Li}[\text{Ni}_x\text{Li}_{(1/3-2x/3)}\text{Mn}_{(2/3-x/3)}]\text{O}_2$ [68]. Computational modeling [69] and spectroscopic investigations [70] show that the Ni and Mn in these materials are in the +2 and +4 oxidation states, respectively. During normal charge processes in an electrochemical cell, nickel is ultimately oxidized to the +4 oxidation state, and Mn remains tetravalent. $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ does not convert to spinel upon cycling, unlike the metastable O3- LiMnO_2 , because no trivalent Mn is ever produced in the structure.

The defect chemistry of $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ also distinguishes it from LiNiO_2 (where nickel is primarily in the +3 oxidation state initially) discussed above. A feature of $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ is anti-site mixing [65–67, 71, 72] in which some Ni^{2+} ions are located on the Li 3a sites, and some Li^+ ions on transition metal 3b sites, that is, $(\text{Li}_{1-x}\text{Ni}_x)_{3a}(\text{Li}_x\text{Ni}_{0.5-x}\text{Mn}_{0.5})_{3b}\text{O}_2$, $x \approx 0.08–0.12$. Mn ions in the transition metal layers preferentially surround the Li ions located in 3a sites to form Li_2MnO_3 -like clusters, and Ni ions occupy sites adjacent to Mn, to form a “flower pattern” (Fig. 4). The anti-site mixing is thought to be a thermodynamically favored feature of the ion ordering and thus intrinsic to the structure. Unlike with LiNiO_2 , simple manipulation of conditions during direct synthesis is therefore not likely to result in a near-ideal layered structure.

$\text{Li}[\text{Ni}_x\text{Li}_{(1/3-2x/3)}\text{Mn}_{(2/3-x/3)}]\text{O}_2$ compounds can be considered solid solutions of Li_2MnO_3 and $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$. Although the discharge capacity between 4.4 and 3.0 V versus Li/Li⁺ drops as the Ni content decreases, the opposite trend is observed after cell charge to 4.8 V and subsequent discharge to 2.0 V [73]. In addition, the Li_2MnO_3 -rich materials exhibit a plateau at about 4.5 V during charge, the length of which is inversely proportional to x . This is thought to be deintercalation of Li ions with concomitant loss of

Battery Cathodes. Figure 4

A transition metal layer in $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ showing the flower pattern. Li is represented by the large gray circles, Mn by small white circles, and Ni by black circles (Used with permission from Ref. [71])

oxygen (for a net loss of Li_2O), similar to what happens when Li_2MnO_3 is charged in an electrochemical cell. This process can result in very high discharge capacities upon subsequent cycles (e.g., 230 mAh/g for $x = 1/3$). An advantage to these materials and related Li-rich materials (where excess lithium replaces some of the transition metal ions on $3b$ sites, but the Mn content still equals that of the Ni content) is decreased cation mixing. This improves rate capability [74] as compared to $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$.

The presence of a relatively large number of Ni ions in the Li $3a$ sites of the $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ structure due to the anti-site mixing has a negative impact on the Li diffusivity, resulting in a low-rate cathode material. $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$, prepared by low-temperature ion exchange of the nearly perfectly layered $\text{NaNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ analog, is capable of sustaining higher discharge currents than samples prepared by conventional methods [75]. However, the most successful method used to address this issue has been to incorporate some cobalt into the structure [76]. The best known of these compounds is $\text{Li}[\text{Ni}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}]\text{O}_2$, sometimes referred to as NMC (Tables 1 and 2). This compound is gradually replacing LiCoO_2 in consumer batteries (in some cases, a mixture of the two are used as the cathode) and is under consideration for some vehicular applications. The voltage profile of NMC versus Li/Li^+ is gradually sloping (Fig. 3), as is typical of many layered compounds, and provides a somewhat

higher capacity than LiCoO_2 below 4.3 V versus Li/Li^+ (typically about 160 mAh/g compared to 140). Capacities in excess of 200 mAh/g can be achieved when cells are charged to higher voltage limits, although this usually results in diminished cycle life.

The oxidation states of Ni, Co, and Mn in as-made $\text{Li}[\text{Ni}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}]\text{O}_2$ are +2, +3, and +4, respectively [77]. First principle calculations suggest that Ni^{2+} is ultimately oxidized to Ni^{4+} during extraction of the first two-thirds of the lithium during electrochemical charging in lithium cells, and oxidation of Co^{3+} to Co^{4+} occurs only during removal of the last one-third [78] (i.e., at high cell potentials). As in $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$, Mn remains inactive throughout normal operating cell voltages. The redox activity of Ni during the extraction of lithium from $\text{Li}[\text{Ni}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}]\text{O}_2$ has been verified by in situ X-ray absorption spectroscopic (XAS) studies, although the details of the participation of Co in the electrochemistry are less clear [79–83]. Charge compensation associated with Co is currently thought to occur, at least partially, at oxygen sites, due to the covalency of the Co–O bonds.

The improved electrochemical properties and better structural, chemical, and thermal stability [84, 85] of $\text{Li}[\text{Ni}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}]\text{O}_2$ compared to LiCoO_2 or NCA render it an attractive replacement cathode material for consumer batteries. Nevertheless, the presence of a significant amount of costly cobalt, albeit in reduced quantities compared to LiCoO_2 , may still make it too expensive for most vehicular applications. Compounds having the general formula $\text{Li}[\text{Ni}_x\text{Co}_{1-2x}\text{Mn}_x]\text{O}_2$ with $x = 0.4$ or 0.45 have recently been developed by Whittingham and coworkers specifically to address the cost issue [86–89]. Although the amount of anti-site mixing increases with larger x , these materials exhibit very good electrochemical performances. The effect of increasing the Ni content of these materials on the thermal stability, especially at high states of charge, remains to be determined, however.

Another approach has been to partially substitute another metal such as aluminum for cobalt [89, 90]. Although the amount of substitution must be kept low to maintain the high specific capacities, both the thermal stability of the delithiated materials [91] and the electrochemical properties [92, 93] appear to be enhanced.

All of the NMCs discussed above contain equal amounts of Ni and Mn, which ensure that the oxidation states of the two metals are primarily +2 and +4, respectively. Recent attempts to increase Mn content in stoichiometric materials having the formula $\text{Li}[\text{Ni}_{0.45-x}\text{Co}_{0.1}\text{Mn}_{0.45+x}]\text{O}_2$ yielded phase mixtures for values of $x > 0.05$ [94] and a solid solution phase for $x = 0.05$. In this compound, $\text{Li}[\text{Ni}_{0.4}\text{Co}_{0.1}\text{Mn}_{0.5}]\text{O}_2$, the extra manganese is in the +3 oxidation state. Unfortunately, this material exhibits poorer capacity retention upon electrochemical cycling and lower rate capability than $\text{Li}[\text{Ni}_{0.45}\text{Co}_{0.1}\text{Mn}_{0.45}]\text{O}_2$. It is, however, possible to form solid solutions between $\text{Li}[\text{Ni}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}]\text{O}_2$ and Li_2MnO_3 to make Li- and Mn-rich materials where the excess Mn is in the +4 oxidation state. As with the related $\text{Li}[\text{Ni}_x\text{Li}_{(1/3-2x/3)}\text{Mn}_{(2/3-x/3)}]\text{O}_2$ compounds, these materials can be electrochemically activated during charge to high potentials in lithium cells. The activation process (deintercalation of Li, concomitant loss of oxygen, and H^+/Li^+ ion exchange) yields electrodes with discharge capacities as high as 290 mAh/g [95, 96]. The very high capacities make these materials interesting for both consumer and automotive applications, and they are now being actively developed (e.g., by Envia Systems, Newark, CA).

Manganese Oxide Spinel

The marked tendency for many manganese oxide phases to convert to spinel structures during lithiation in electrochemical cells, or upon heating with a lithium source, attests to the stability of this structure in the Li-Mn-O system. The stoichiometric spinel, LiMn_2O_4 , is easily synthesized in air from a variety of Li and Mn-containing precursors. Figure 2b shows its cubic structure (space group $\text{Fd-}3\text{m}$), where Li ions occupy tetrahedral $8a$ sites and Mn is located in octahedral $16d$ sites in a ccp array of oxygen anions. In addition, there are vacant tetrahedral and octahedral interstitial sites in the three-dimensional structure that provide pathways for lithium diffusion.

Early work [97] showed that it is possible to remove lithium from LiMn_2O_4 using a mild acid treatment. During this process, Mn is oxidized from an average +3.5 oxidation state to +4, and $\lambda\text{-MnO}_2$, which retains

the spinel framework, is formed (Eq. 1). In addition, some dissolution of Mn occurs:

Oxidative extraction of lithium from the tetrahedral $8a$ sites of LiMn_2O_4 to form $\lambda\text{-MnO}_2$ in a lithium cell [98, 99] was subsequently demonstrated to occur slightly above 4 V. It is also possible to insert lithium into the vacant octahedral sites of LiMn_2O_4 either chemically or electrochemically, with concomitant reduction of Mn. When carried out in a cell with a lithium anode, this process occurs below 3 V, and the discharge profile is flat, indicative of a two-phase reaction. The tetragonally distorted phase $\text{Li}_2\text{Mn}_2\text{O}_4$ (space group $\text{I4}_1/\text{amd}$) is formed due to the cooperative Jahn–Teller effect, which occurs when more than half the manganese is in the form of d^4 Jahn–Teller Mn^{3+} ions. The phase transition results in a 16% increase in the c/a ratio [100] ($a = c = 8.248 \text{ \AA}$ in LiMn_2O_4 ; $a = 8.007 \text{ \AA}$, $c = 9.274 \text{ \AA}$ in $\text{Li}_2\text{Mn}_2\text{O}_4$). In theory, lithium cells containing LiMn_2O_4 can either be charged or discharged initially, and then cycled over a composition range of $0 \leq x \leq 2$ in $\text{Li}_x\text{Mn}_2\text{O}_4$ to give a total specific capacity of 285 mAh/g. Figure 5 shows the voltage profile of a Li/modified LiMn_2O_4 cell assembled in the author's laboratory, after discharging

Battery Cathodes. Figure 5

Discharge profile of a Li/modified- LiMn_2O_4 cell at 0.1 mA/cm^2 . Cell was initially discharged to 2 V and then charged to 4.3 V. This was the third discharge between 4.3 and 2.0 V

into the 3 V region and full recharge. Both 4 and 3 V plateaus are evident; although the overall capacity is somewhat lower than the theoretical value.

The large anisotropic volume change associated with formation of tetragonal $\text{Li}_2\text{Mn}_2\text{O}_4$ results in particle disintegration and loss of connection within the composite electrode. This causes such a rapid loss of capacity that, in practice, the cycle lives of cells containing LiMn_2O_4 discharged even a few times into the 3 V region are greatly compromised. In contrast, the extraction of lithium from LiMn_2O_4 above 4 V versus Li/Li^+ maintains the cubic structure and results in smaller volume changes. For this reason, discharge is typically limited to the 4 V plateau (Fig. 3), which exhibits much better reversibility. The theoretical capacity associated with this plateau is 148 mAh/g, although it is difficult to fully extract all the lithium, resulting in somewhat lower practical values.

From the early 1990s onward, intensive efforts were devoted to the development of LiMn_2O_4 for lithium-ion batteries, particularly at Bellcore Laboratories [101–103]. Although limiting discharges to the 4 V plateau resulted in much better cycling than when both the 3 and 4 V plateaus were utilized, gradual capacity fading was still observed [104]. This behavior was attributed to several factors, including irreversible side reactions with the electrolyte due to the high potential, loss of oxygen from the delithiated spinel, dissolution of Mn, and production of tetragonal $\text{Li}_2\text{Mn}_2\text{O}_4$ at particle surfaces, particularly at high discharge rates [100, 105].

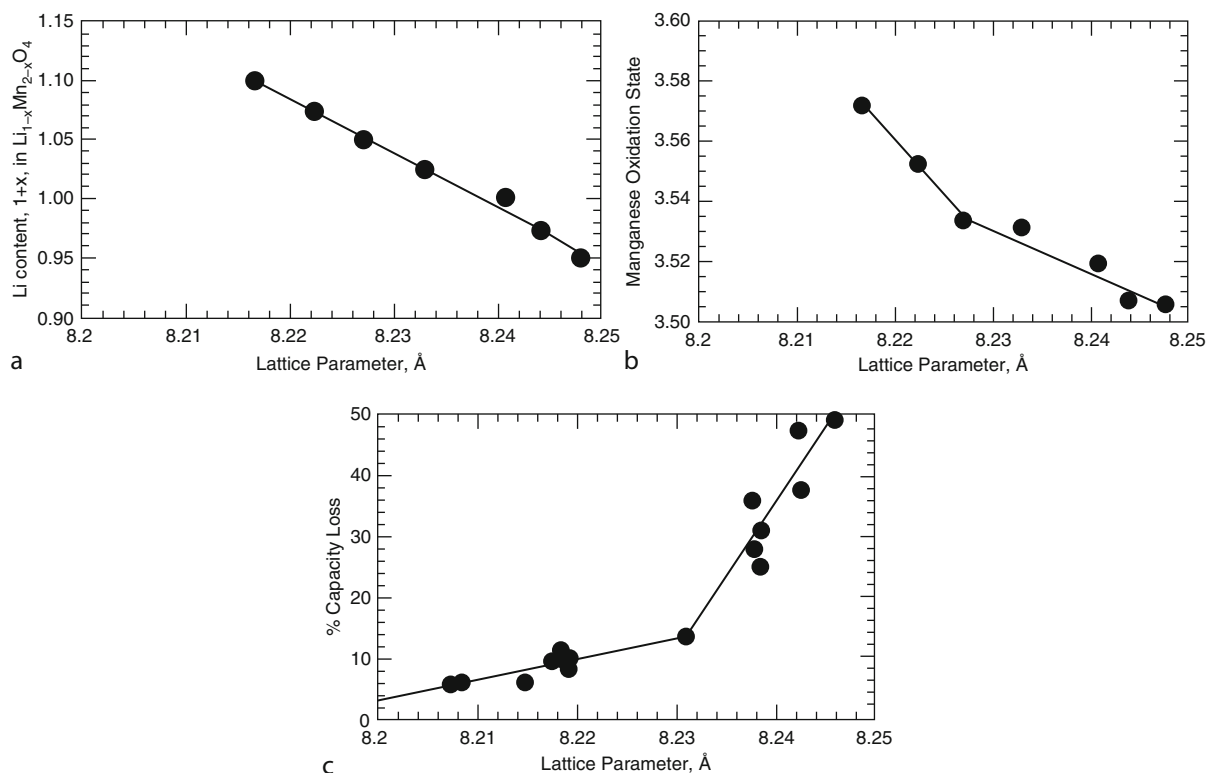

Partial substitution of Mn to form $\text{LiM}_x\text{Mn}_{2-x}\text{O}_4$ improves capacity retention [106–112]. Of particular interest are the lithium-substituted materials having the general formula $\text{Li}_{1+x}\text{Mn}_{2-x}\text{O}_4$. As lithium is substituted for manganese on the $16d$ sites (x is increased), the average oxidation state of the latter rises. This effectively decreases the 4 V capacity in proportion to the amount of substitution but results in a higher average oxidation state of the Mn at the end-of-discharge. This ameliorates the tendency to form the tetragonally distorted phase under nonequilibrium conditions such as rapid discharging, because this occurs only when the Mn oxidation state falls below an average of 3.5. Because Mn is fully oxidized before all the lithium can be extracted from $8a$ sites, side reactions are suppressed. Finally, dissolution of Mn

decreases because this phenomenon is dependent on the concentration of trivalent ions.

Li substitution and the attendant increase in Mn oxidation state in the as-made $\text{Li}_{1+x}\text{Mn}_{2-x}\text{O}_4$ compounds decrease the lattice parameter, a (Fig. 6a and b). The magnitude of this value correlates closely with the amount of capacity loss upon cycling (Fig. 6c), so that it can be used to predict the cycling behavior of the spinel materials [113]. In particular, improvements are most marked when $a \leq 8.23$ Å. Because the cycling behavior is so much better than LiMn_2O_4 , nearly all commercial manganese oxide spinel materials (LMOs) made today are lithium substituted. These have theoretical specific capacities of 100–120 mAh/g (Table 1), somewhat lower than that for LiMn_2O_4 .

The maximum possible substitution in $\text{Li}_{1+x}\text{Mn}_{2-x}\text{O}_4$ corresponds to $x = 1/3$ (the compound $\text{Li}_{4/3}\text{Mn}_{5/3}\text{O}_4$ or $\text{Li}_4\text{Mn}_5\text{O}_{12}$), at which point all of the Mn is in the +4 oxidation state and there is no 4 V capacity, because oxidative extraction of lithium cannot occur. Nevertheless, it is possible to insert lithium reversibly into octahedral $16c$ sites at about 2.9 V versus Li/Li^+ until a composition of $\text{Li}_7\text{Mn}_5\text{O}_{12}$ is reached, for a total of 156 mAh/g [114, 115]. The cubic symmetry is maintained until about $\text{Li}_{6.5}\text{Mn}_5\text{O}_{12}$, at which point Mn is reduced to an average oxidation state of 3.5 and the cooperative Jahn–Teller effect induces a tetragonal distortion. Because this process occurs only at the end-of-discharge, $\text{Li}_4\text{Mn}_5\text{O}_{12}$ exhibits much better cycling behavior on the 3 V plateau than does LiMn_2O_4 . However, the low operating voltage and capacity, and the inability to extract lithium makes $\text{Li}_4\text{Mn}_5\text{O}_{12}$ impractical for Li-ion batteries.

It is also possible to prepare cation-deficient or defect spinels, $\text{Li}_{1-x}\text{Mn}_{2-2x}\text{O}_4$ [114]. The cation vacancies increase the average oxidation state of Mn and decrease the capacity above 4 V in favor of that below 3 V, proportionally with x . In the end-member compound $\text{Li}_2\text{Mn}_4\text{O}_9$ (corresponding to $x = 0.11$ in $\text{Li}_{1-x}\text{Mn}_{2-2x}\text{O}_4$), all Mn is tetravalent, and lithium cannot be extracted, so that there is no capacity at 4 V. Lithium can be inserted below 3 V versus Li/Li^+ , to a maximum composition of $\text{Li}_5\text{Mn}_4\text{O}_9$. Although the theoretical capacity (213 mAh/g) is higher than that of $\text{Li}_4\text{Mn}_5\text{O}_{12}$, approximately 1/3 of it is associated with the formation of the Jahn–Teller distorted tetragonal phase.

Battery Cathodes. Figure 6

(a) The variation of the lattice parameter, a , with the lithium content of $\text{Li}_{1+x}\text{Mn}_{2-x}\text{O}_4$; (b) the variation of lattice parameter with the average Mn oxidation state in $\text{Li}_{1+x}\text{Mn}_{2-x}\text{O}_4$; and (c) relationship between capacity loss after 120 cycles and the lattice parameter in $\text{Li}_{1+x}\text{Mn}_{2-x}\text{O}_4$ (Used with permission from Ref. [113])

In principle, defect spinels with values of $x < 0.11$ should cycle on the 4 V plateau better than LiMn_2O_4 for the same reasons as the lithium-rich stoichiometric spinels. In practice, it is difficult to control the degree of non-stoichiometry during synthesis, so these materials are not of interest commercially.

In spite of the improved performance exhibited by the lithium-substituted spinels, capacity fading upon cycling is still observed in electrochemical cells, particularly at elevated temperatures (55°C) [116–121]. This has negative implications particularly for vehicular applications, where batteries may be subjected to a wide variety of operating and storage conditions, including very warm environments. The dissolution is associated with Mn^{3+} disproportionation (Eq. 2) in the presence of acidic components of the

LiPF_6 /organic carbonate electrolyte solutions used in Li-ion batteries.

Loss of manganese leads to the formation of a defect spinel structure with reduced or no 4 V capacity [104, 116–121]. Additionally, proton exchange [116–121], phase separation, film formation, and precipitation of MnO and MnF_2 may occur, increasing cell impedance and exacerbating the capacity fading. More significantly, dissolved Mn^{2+} can cross over to the anode, become reduced, and precipitate as the metal, increasing the charge-transfer resistance and disrupting the critical SEI layer [122, 123]. The graphite anode is

markedly more sensitive to this effect than lithium is. Thus, assessment of spinel cathodes to determine the effectiveness of an approach to improve resistance to dissolution should ultimately be carried out in a full cell configuration rather than in lithium half-cells.

Some methods designed to address the problem of spinel dissolution include coating of particles [124, 125] and the use of new non-fluorinated salts such as lithium bis(oxalato)borate (LiBOB) which do not generate HF in situ [126–128]. Interestingly, dissolution of manganese appears to be suppressed in electrodes where LMO is mixed with an NMC [129]. Although the cycling behavior of Li-ion cells with spinel electrodes is still inferior to that of devices containing alternative commercial cathode materials (Table 2), other aspects of performance such as rate capability and safety [33–36, 130], the wide availability of manganese precursors, and the potential for low cost make LMO attractive especially for vehicular applications. Thus, at least one battery manufacturer focused on vehicle technologies (e.g., Enerdel, Indianapolis, IN) is pursuing the development of Li-ion batteries with spinel cathodes and hard carbon anodes (which are less sensitive to the effects of manganese dissolution than graphite).

Several lithium-containing oxide spinels having transition metals other than Mn can also be synthesized. One example is LiCo_2O_4 , which can be prepared from a low-temperature form of LiCoO_2 [131]. (The latter, known as LT- LiCoO_2 , has a structure intermediate between that of a spinel and layered compound). Another is LiNi_2O_4 [25]. Unlike LiMn_2O_4 , the electrochemical characteristics of most of these spinels are inferior to those of the layered analogs, so that they are not of technological interest as cathode materials. However, $\text{Li}_4\text{Ti}_5\text{O}_{12}$ (LTO), which, because of its voltage properties, functions as an anode material, demonstrates excellent cycling performance. Although the energy density is lower than that of graphite, it does not require the formation of an SEI. Thus, it is also an attractive match for LMO cathode materials. Batteries with LTO anodes and LMO or other high-voltage cathodes may find utility in HEVs, which do not require as high an energy density as pure EVs.

The intensive search for substituted lithium manganese spinels with better cycling performance led to

the discovery of several materials having capacity near 5 V versus Li/Li^+ . These include spinels substituted with Cr, Fe, Cu, Co, or Ni [132–136]. In most cases, these materials exhibit a plateau near 4 V as well as a second plateau near 5 V, with the magnitude of the latter increasing with larger x in $\text{LiM}_x\text{Mn}_{2-x}\text{O}_4$ (where $M = \text{Cr, Fe, Cu, Co, or Ni}$). The 4 V capacity is associated with the usual $\text{Mn}^{3+}/\text{Mn}^{4+}$ spinel redox couple, whereas the higher voltage plateau is associated with redox processes of the substituting metal. Interestingly, the compound $\text{LiNi}_{1/2}\text{Mn}_{3/2}\text{O}_4$ has very little 4 V capacity, unlike other $\text{LiM}_{1/2}\text{Mn}_{3/2}\text{O}_4$ spinels [137] (Fig. 7).

In the case of $\text{LiNi}_{1/2}\text{Mn}_{3/2}\text{O}_4$, nearly all of the Mn is tetravalent [136], so that further oxidation is not possible. The specific capacity of 147 mAh/g at 4.7 V is associated with $\text{Ni}^{2+}/\text{Ni}^{4+}$ redox processes. The high energy density and high voltage makes this material attractive for vehicular applications, because fewer cells need to be connected in series to make the 300 V packs used in electric vehicles. This simplifies engineering, results in comparatively higher energy density on the system level because less hardware is required, and lowers costs. ETV Motors of Herzliya, Israel, is one company actively developing $\text{LiNi}_{1/2}\text{Mn}_{3/2}\text{O}_4$ batteries for this purpose.

The very high potential at which this cathode operates, however, presents considerable challenges for cycle life. Although conventional carbonate-based electrolytes used in Li-ion batteries have, in principle, excellent oxidative stability, the presence of impurities such as water may contribute to side reactions that decrease resistance to irreversible oxidation, resulting in shortened battery lifetimes. In addition, cell components such as carbon additives used to improve conductivity in composite cathodes, or surfactants that aid in wetting may oxidize irreversibly at high potentials, and current collectors may corrode. Thus, cycling is usually restricted to a voltage range below about 4.3 V versus Li/Li^+ (4.2 V in cells with graphite anodes). Stringent purification of electrolytes and the use of special protective additives are allowing gradual extension of this range. In addition, the development of new electrolytes containing ionic liquids or sulfolanes is expected to enable high-voltage cell operation, although the choice of anode may then be restricted

Battery Cathodes. Figure 7

Slow-scan voltammetry of $\text{Li}/\text{LiMn}_{1/2}\text{Mn}_{3/2}\text{O}_4$ cells with $M =$ (a) Cr, (b) Mn, (c) Fe, (d) Co, (e) Ni, and (f) Cu at a rate of 0.2 mV/s using 1 M LiPF_6 in 1:1 v/v EC/DEC electrolyte (Used with permission from Ref. [137])

to LTO or other materials that do not require SEI formation. Other strategies to prolong the cycle life of cells containing $\text{LiNi}_{1/2}\text{Mn}_{3/2}\text{O}_4$ include treating active material particles with protective coatings to minimize direct contact with electrolyte solutions [138–140], or partial substitution of Ni or Mn with other cations such as Ti, Mg, or Zn [141–143].

Synthesis of $\text{LiNi}_{1/2}\text{Mn}_{3/2}\text{O}_4$ is normally carried out at high temperatures to ensure good crystallinity and to lower the surface area and thus minimize reactivity with electrolyte solutions and other components. Under these conditions, oxygen loss may occur, leading to the formation of a non-stoichiometric material

($\text{LiNi}_{1/2}\text{Mn}_{3/2}\text{O}_{4-x}$) containing some Mn^{3+} in the structure. Additionally, a rock salt impurity, $\text{Li}_x\text{Ni}_{1-x}\text{O}$, is also produced. Annealing at 700°C partially reverses the oxygen loss, but the telltale 4 V capacity indicative of the presence of electroactive Mn^{3+} can often be observed in cells made with these materials (e.g., in Fig. 7e). Substitution with other metals, as discussed in the papers listed in Refs. [141–143], often decreases the amount of Mn^{3+} in these compounds, which may play a role in the observed improvements in cycling.

If the sample is cooled slowly during synthesis, an ordered phase can be produced (space group $P4_332$ with Ni in $4b$ sites and Mn in $12d$ sites [144]). The

electrochemical properties (in particular, rate capability) of the ordered phase are inferior to those of the disordered non-stoichiometric phase [145, 146]. The mixed Mn valency in the disordered Fd-3m phase leads to an increase in the electronic conductivity of about 1.5 orders of magnitude compared to that of the ordered material. This is thought to be responsible for the increased rate capability of the former compared to the latter.

The presence of electroactive Mn in disordered $\text{LiNi}_{1/2}\text{Mn}_{3/2}\text{O}_4$ suggests that dissolution may be problematic, as it is with the LiMn_2O_4 variants. In spite of this and the high operating voltages, extremely stable cycling has been observed in full cell configurations, albeit with $\text{Li}_4\text{Ti}_5\text{O}_{12}$ anodes [147].

LiFePO₄ and Other Phospho-olivines

In 1997, Goodenough and coworkers reported on the electrochemical properties of a new class of cathode materials known as the phospho-olivines [148], which adopt the orthorhombic structure (space group Pnma) shown in Fig. 2c. In the case of LiFePO_4 (triphylite), Li^+ and Fe^{2+} occupy octahedral sites, and P is located in tetrahedral sites in a somewhat distorted hexagonal close-packed (hcp) oxygen array. The FeO_6 octahedra share corners and LiO_6 octahedra share edges along tunnels down the *b*-axis, through which the Li ions can diffuse. Extraction and reinsertion of Li from LiFePO_4 proceeds at about 3.45 V in a lithium cell with a theoretical specific capacity of 170 mAh/g. The potential is independent of the composition *x* in Li_xFePO_4 (i.e., the voltage profile is flat, Fig. 3) indicating that a two-phase reaction occurs. In situ X-ray diffraction and Mossbauer experiments on Li/LiFePO₄ cells [149] show that the two relevant phases are triphylite and FePO_4 , also known as heterosite (Eq. 3).

Initial reports on the electrochemical characteristics of LiFePO_4 emphasized its poor rate capability and the lower than expected utilization in lithium cells even when discharged at low current densities (e.g., only about 60% in Ref. [149]). This was attributed to the low electronic conductivities of both the triphylite and heterosite phases [150]. Coating particles with carbon

ameliorates the low conductivity and result in better rate performance [151]. This is most conveniently achieved by including a carbon source during initial synthesis of the LiFePO_4 sample. The presence of carbon or carbon-containing precursors during calcination in an inert atmosphere has several additional beneficial effects; it retards grain growth, resulting in small particles that allow rapid extraction of Li ions, and prevents formation of Fe^{3+} -containing impurities. It also allows the use of easy-to-handle, low-cost, Fe^{3+} -containing starting materials such as iron nitrate, which are reduced during the heating process [152].

In practice, many lab-synthesized samples of LiFePO_4 contain carbon, due to the use of precursors such as iron oxalate [153]. Even small amounts of carbon can result in drastic sample color changes from the off-white of native LiFePO_4 (Fig. 8). The electrochemical performance is also greatly affected by the carbon content, although this also depends on the distribution of carbon over particle surfaces and details of its structure [154–157]. Carbons produced in situ during synthesis of LiFePO_4 are disordered due to the relatively low calcination temperatures (generally, 600–700°C). Disordered carbons are less conductive than graphite, and conductivity depends on the size and number of graphene domains. The use of graphitization catalysts (often containing iron) improves the conductivity of coatings by several orders of magnitude, and can also result in co-production of carbon nanotubes or fibers, which wire particles together [158, 159]. The result is that very small amounts of carbon, often less than 2 wt.%, are sufficient to produce high-rate LiFePO_4 samples. This is important because too much lightweight carbon adversely affects the tap densities of LiFePO_4 composites, further decreasing the already somewhat low energy density [160].

Battery Cathodes. Figure 8

Photographs of LiFePO_4 samples containing varying amounts of carbon (Used with permission from Ref. [153])

The changes in sample color, increases in bulk conductivities, and improved electrochemical performance induced by the presence of very small amounts of carbon (or other highly colored impurities) complicate the interpretation of results of doping experiments intended to increase the intrinsic conductivity of LiFePO_4 . A color change from off-white to black or gray should not be regarded as proof-positive of successful doping and increased intrinsic electronic conductivity, for the reasons described above. Even when carbonaceous precursors are not used, the use of organic solvents or plastic containers during grinding or other processing steps may introduce carbon. Early claims of successful low-level aliovalent substitution [161] on the Li sites of LiFePO_4 , resulting in greatly enhanced conductivities and electrochemical performance, may have been a fortuitous consequence of well-distributed electronically conductive impurities such as carbon and metal-rich phosphides [162–166]. Recent studies of the defect chemistry of LiFePO_4 show that substitution of multivalent ions on the Li site is very limited, and always accompanied by lithium vacancies, so that no mixed valency for iron occurs [167]. Earlier computational modeling of the defect, dopant, and Li transport properties of LiFePO_4 [168] indicates that substitution of multivalent ions on Li or Fe sites (other than divalent ions on the latter) is not energetically favored. It was predicted that the most likely type of defect is the Li-Fe anti-site pair, in which Li^+ ions are located on Fe^{2+} sites and are balanced by an equal number of Fe^{2+} ions on Li sites. Recent work, however, shows that there is a marked asymmetry between the number of Fe ions on Li sites and vice versa [169–171]. Very few lithium atoms can be accommodated on iron sites. More commonly, Fe ions on Li sites are accompanied by a small number of vacancies, to form $[\text{Li}_{1-2x}\text{Fe}_x]\text{FePO}_4$. The presence of relatively immobile multivalent ions on Li sites interferes with fast Li diffusion, since LiFePO_4 is essentially a one-dimensional ion conductor [172–174]. Likewise, a large number of anti-site defects are likely to impact electrochemical performance adversely [175, 176] as is seen in Refs. [169–171]. At any rate, it is apparent that near room temperature, only a relatively small concentration of vacancies or interstitial defects is possible.

Carbon coatings, although convenient for the reasons stated above, are not absolutely necessary to assure good electrochemical performance [177], as long as particle sizes are kept small and particle size distributions are narrow. Nanostructuring reduces diffusion distances and ameliorates the effects of low electronic conductivity, allowing full discharge at even moderate to high rates. Subtle changes in the discharge characteristics of LiFePO_4 samples occur as particle size is decreased, most notably, a stronger dependence of voltage upon composition (x in Li_xFePO_4) close to the end-of-charge and end-of-discharge, implying solid-solution behavior [178, 179]. Other researchers have observed XRD, neutron diffraction, and electrochemical evidence of a small degree of lithium non-stoichiometry in larger Li_xFePO_4 particles at both composition extremes [180, 181], as illustrated in Fig. 9.

The existence of a small degree of non-stoichiometry (and thus mixed valence states for iron) may explain why this system is electroactive, given that both end members have such poor electronic conductivity. It should be noted, however, that kinetic effects, surface impurities, and the presence of defects [179, 182–184] also influence the shape of the Li/ LiFePO_4 discharge profile. This makes it hard to determine what the exact compositional ranges of solid-solution behavior are at room temperature from the electrochemical data alone. Complications from the effects of strain also make the interpretation of diffraction data difficult.

Experiments conducted on heated $\text{LiFePO}_4/\text{FePO}_4$ mixtures of varying concentrations [185, 186] show that solid solutions form from $0 \leq x \leq 1$ in Li_xFePO_4 at elevated temperatures, however. A representative phase diagram is shown in Fig. 10. The solubility limits of lithium in heterosite and vacancies in triphylite are approximated in the figure, because of the uncertainties outlined above. Additionally, due to slow kinetics, the exact temperature boundaries are not known, explaining the differences observed by various researchers. Depending upon the initial concentration, and details of the crystal sizes and morphologies, metastable lithium-deficient phases can persist for remarkably long times after cooling [187].

The mechanism of the $\text{LiFePO}_4/\text{FePO}_4$ electrochemical reaction has been described using a shrinking

Battery Cathodes. Figure 9

Scheme of the discharge processes of Li_xFePO_4 , showing solid-solution behavior close to $x = 0$ and $x = 1$ (Used with permission from Ref. [180])

core model [188], as depicted in Fig. 9. During discharge, lithium initially inserts into FePO_4 to form the solid-solution $\text{Li}_\alpha\text{FePO}_4$ phase, where α is close to 0. Upon further passage of current, a shell of a lithium-rich material ($\text{Li}_{1-\beta}\text{FePO}_4$) is produced on the surface, over a core of $\text{Li}_\alpha\text{FePO}_4$. As the reaction continues to progress, the shell grows at the expense of the core, and the interface between the two phases shrinks, until complete conversion to $\text{Li}_{1-\beta}\text{FePO}_4$ occurs. Further lithiation produces LiFePO_4 at the end-of-discharge. The entire process is reversed upon charge. The anisotropy of lithium diffusion in LiFePO_4 [172–174], however, complicates the interpretation of the shrinking core model. A transmission electron microscopy (TEM) study of partially delithiated large plate-like particles [189] show that ordered domains of FePO_4 and LiFePO_4 alternate in the ac plane, separated by narrow disordered (but not amorphous) regions, where lithium mobility is enhanced. The phase transformation proceeds in the direction of the a -axis at dislocation lines that run parallel to the c -axis, consistent with one-dimensional Li^+ diffusion in the b -direction (Fig. 11). This somewhat resembles an early “mosaic” model proposed by Andersson et al. as

an alternative to the shrinking core model [190]. These observations also suggest that the best rate performance can be achieved with particles that are thin in the direction of Li diffusion (b -axis), but that nanostructuring in other directions may not be required.

In another recent study [191] using high-resolution electron energy loss spectroscopy (EELS) on a chemically prepared sample, a different distribution of the two phases in a partially delithiated particle was observed. In this case, LiFePO_4 was present only at the edges with FePO_4 located in the interior (but not on surfaces of the ac planes) of plate-like particles significantly smaller than those studied in Ref. [189]. This is consistent with a progressive emptying or filling of Li channels oriented along the b -axis, with the front between the two phases moving perpendicular to the ac plane. No disordered regions at the phase boundaries were detected, however. This lack of evidence for solid-solution behavior argues against a shrinking core mechanism, which requires that at least a small degree of non-stoichiometry exist in the system.

Variations in particle sizes and morphologies, as well as in the concentration of defects, may well

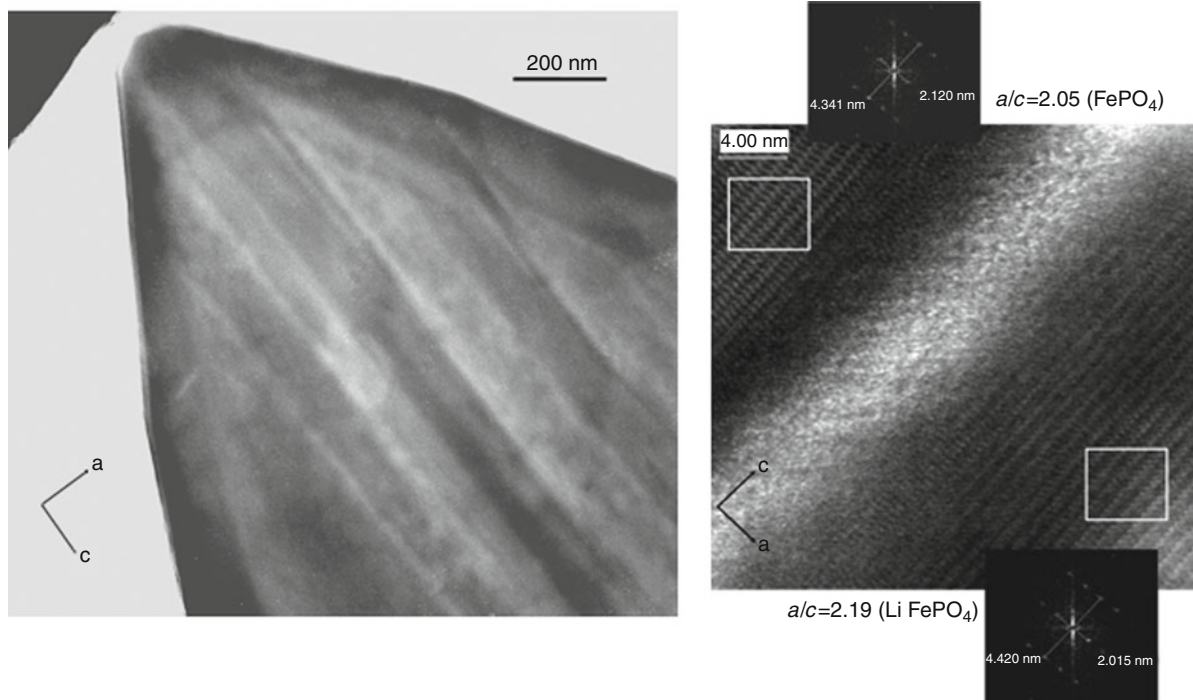

influence the progression of the delithiation reaction during chemical oxidation and explain these differing results. In electrochemical cells with composite

Battery Cathodes. Figure 10

Phase diagram of the Li_xPO_4 system, where T, H, and D denote triphylite, heterosite, and disordered (but not amorphous) phases, respectively (Used with permission from Ref. [186])

electrodes, the reaction may nucleate preferentially at sites where contact with conductive carbon additives or coatings and the electrolyte solution is the closest, leading to a different pattern of phase distributions than is seen in the chemically delithiated samples, where nucleation can occur at numerous sites simultaneously. In partially delithiated Li_xFePO_4 samples recovered from electrochemical cells, no mixed-phase nanoparticles were observed, leading the researchers to surmise that the reaction front propagates much more rapidly than nucleation [192]. A recent kinetic study also indicates that the $\text{LiFePO}_4/\text{FePO}_4$ transformation is controlled by a phase-boundary reaction [193]. However, newly discovered evidence of intercrystallite ionic transport, leading to a redox reaction between delithiated and lithiated particles and subsequent equilibration [194] complicates the interpretation of these results. Moreover, areas of composite electrodes with poor electronic connectivity may be electrochemically inactive, leading to islands of unreacted LiFePO_4 .

Battery Cathodes. Figure 11

Left: TEM image showing a partially delithiated crystal with the global composition $\text{Li}_{0.5}\text{FePO}_4$, showing domains of LiFePO_4 and FePO_4 aligned along the c -axis. Right: High-resolution TEM image with Fourier transforms of the boxed areas, identifying the two phases (Used with permission from Ref. [189])

In that case, all of the lithium will be extracted from LiFePO_4 in better connected areas, and mixtures of FePO_4 and LiFePO_4 will be observed, as in Ref. [192].

While the actual mechanism of the $\text{LiFePO}_4/\text{FePO}_4$ transformation remains a subject of debate, it seems clear that the shrinking core model does not apply to the primary particles themselves. The model may, however, still be applicable on a larger scale, for example, to the secondary particles comprised of agglomerates.

Over the past decade, better control of synthesis parameters, the use of conductive coatings, and nanostructuring have transformed LiFePO_4 from a poorly performing material to one of the most attractive cathodes for Li-ion batteries. LiFePO_4 appears to be particularly well suited to high-power applications including power tools and vehicle propulsion. A recent study shows that extraordinarily high charge and discharge currents can be sustained in cells designed so that a modified LiFePO_4 limits rate [195]. (While these devices are not practical for real-world use, they serve to demonstrate the intrinsic rate capability of LiFePO_4 without interference from mass transfer limitations in other cell components). There have been reports [196, 197] of iron dissolution in LiPF_6 -containing electrolytes leading to capacity fading at elevated temperatures (analogous to the problems observed with manganese oxide spinels), although this may be due to the presence of iron-containing surface impurities such as Fe_2P rather than to the LiFePO_4 itself. The thermal properties of the $\text{LiFePO}_4/\text{FePO}_4$ system are a particularly attractive feature, leading to enhanced safety (LFP, Table 2). Upon heating, FePO_4 produced by charging LiFePO_4 transforms to the thermodynamically favored trigonal form (α -quartz structure). While this reaction is irreversible and leads to loss of capacity, it progresses without evolution of oxygen [198]. This is in contrast to transition metal oxides, all of which lose oxygen to some degree at high states-of-charge. This makes this cathode especially appealing for traction applications, where safety is paramount.

Because LiFePO_4 is less dense than the layered oxides or spinels (the crystallographic density is 3.6 g/cm^3 compared to about 5 g/cm^3 for the oxides), and the potential versus lithium is lower, the energy density is less than that of the oxides (Table 2). The specific energy, in contrast, is competitive with LMO (Table 1), but for many applications, the energy per

unit volume matters more than per weight. The discharge potential of the isostructural LiMnPO_4 is about 0.5 V versus Li/Li^+ higher than that of LiFePO_4 [199], which increases the specific energy by about 15%. Unfortunately, this material is even less dense than LiFePO_4 (3.4 g/cm^3), and the conductivity appears to be several orders of magnitude lower [200, 201]. Synthetic procedures used to produce nanoparticulate LiMnPO_4 and variants include sol-gel, precipitation, combustion techniques, spray pyrolysis, and hydrothermal or solvothermal (polyol process) methods [176, 202–208]. For samples calcined in air for the sake of convenience, a fair amount of carbon is generally added after synthesis to offset the low conductivity. Coating can also be achieved via incorporation of carbonaceous precursors or elemental carbon during heat treatment under inert atmosphere, as with LiFePO_4 . Electrochemical performance improves as the average primary particle size decreases [209]. Partial Mg substitution on the Mn site is also beneficial [208, 210–212]. This effect has been attributed to stabilization against strain associated with the Jahn–Teller distortion of Mn^{3+} ions in the delithiated phase, as well as decreased volume changes upon cycling. The best results reported so far have been for solvothermally prepared powders (polyol process) embedded in a carbon matrix [213]. Still, the rate capability of LiMnPO_4 is not as impressive as that of LiFePO_4 , and many of the strategies employed to improve the electrochemistry (Mg substitution, addition of large amounts of carbon, nanostructuring) reduce the already fairly small energy density advantage. The disappointing performance has been variously attributed to poor transport properties in either the bulk LiMnPO_4 or MnPO_4 phases, the instability of the MnPO_4 phase itself, or surface effects [201, 214, 215]. While the voltage profile of LiMnPO_4 is flat during charge and discharge, indicating a two-phase process, evidence of solid-solution behavior near the MnPO_4 limit has been observed [216]. As with the $\text{LiFePO}_4/\text{FePO}_4$ system, the non stoichiometry may enable the electrochemical activity. However, no solid-solution behavior near the LiMnPO_4 end of the phase diagram has yet been detected.

Although the performance characteristics of the $\text{LiMnPO}_4/\text{MnPO}_4$ system may improve with further work, one troubling aspect of this electrode is its

thermal instability in the charged state. Unlike LiFePO_4 , MnPO_4 evolves oxygen gas upon heating to 200°C and decomposes to form $\text{Mn}_2\text{P}_2\text{O}_7$ [217, 218]. The instability of MnPO_4 is probably related to the strong Jahn–Teller distortion of the Mn^{3+} ion. LiMnPO_4 is therefore less attractive than LiFePO_4 in terms of safety, and does not have better performance characteristics than the metal oxides. Charging is also somewhat problematic, because high over-potentials are required due to the kinetic limitations. Thus, it seems unlikely that this cathode material will prove useful for traction batteries in the near term, although other applications may be feasible.

Phospho-olivine compounds containing Co or Ni also exist. LiCoPO_4 exhibits electrochemical activity at about 4.8 V versus Li/Li^+ [219, 220]. LiNiPO_4 is predicted to discharge at about 5.1 V in a lithium cell, but appears to be nearly completely inactive [221]. Neither of these is likely to be used as cathodes for lithium-ion batteries in the near term in part because of the very high voltages needed to charge the materials, which present a number of practical problems.

Solid solutions containing a mixture of transition metals can be prepared over a wide composition range [176]. $\text{Li}[\text{Mn}_y\text{Fe}_{1-y}]\text{PO}_4$ compounds exhibit two plateaus in the discharge profile at about 4.1 and 3.45 V versus Li/Li^+ with their relative magnitudes proportional to the amounts of Mn and Fe, respectively [148]. In general, for $y < 0.8$, the mixed metal phospho-olivines appear to undergo more facile electrochemical reactions than the pure end-member phase, LiMnPO_4 [215, 222]. A study of the delithiation reactions of these phases [223] suggested that the system is single phase when $x < 1 - y$, but biphasic over the 4.1 V plateau (corresponding to the $\text{Mn}^{2+}/\text{Mn}^{3+}$ redox couple). A later synchrotron diffraction study [224] showed two two-phase regions roughly coinciding with the two plateaus and a narrow solid-solution region between $x = 0.55$ and 0.67 for $\text{Li}_x\text{Mn}_{0.6}\text{Fe}_{0.4}\text{PO}_4$, $_x\text{Mn}_{0.6}\text{Fe}_{0.4}\text{PO}_4$, corresponding to the steeply sloping portion of the discharge profile between the plateaus.

Other mixed transition metal phospho-olivines have been prepared containing Ni and Co [220] and Fe, Mn, and Co [225–227]. In the case of the $\text{Li}[\text{Ni}_y\text{Co}_{1-y}]\text{PO}_4$, only one plateau was observed at 4.8 V, corresponding to the $\text{Co}^{2+}/\text{Co}^{3+}$ redox couple. The only effect of the Ni substitution is to reduce the

Battery Cathodes. Figure 12

Charge and discharge of a $\text{Li}/\text{LiMn}_{1/3}\text{Fe}_{1/3}\text{Co}_{1/3}\text{PO}_4$ cell, showing three distinct plateaus corresponding to the redox of Co (4.8 V), Mn (4.1 V), and Fe (3.45 V) (Used with permission from Refs. [225–227])

overall capacity, demonstrating the poor electro-activity of Ni in the phospho-olivine structure. In lithium cells containing $\text{LiMn}_{1/3}\text{Fe}_{1/3}\text{Co}_{1/3}\text{PO}_4$, on the other hand, three distinct electrochemical features are observed, corresponding to redox processes of the three types of transition metals (Fig. 12). Interestingly, the reaction appears to be single phase over the entire composition range, $0 \leq x \leq 1$ in $\text{LiMn}_{1/3}\text{Fe}_{1/3}\text{Co}_{1/3}\text{PO}_4$, and the redox potentials of the $\text{Fe}^{2+}/\text{Fe}^{3+}$ and $\text{Co}^{2+}/\text{Co}^{3+}$ couples are slightly shifted compared to the corresponding LiMPO_4 electrodes containing only one metal. The manganese redox processes appear to be more sluggish than those of iron and cobalt, and at higher discharge rates, the electrochemical feature at 4.1 V disappears. Tailoring of the voltage profile by incorporating multiple metals in the olivine structure may have practical use as a state-of-charge indicator for vehicular batteries (acting much like the gas gauge in conventional combustion engine automobiles).

Other Phosphates and Poly-anionic Compounds

There are many other transition metal-containing poly-anionic compounds with structures amenable to lithium insertion processes. Among these are numerous materials with the Nasicon structure

(Nasicon stands for sodium superionic conductor and originally referred to $\text{Na}_{1+x}\text{Zr}_2\text{P}_{3-y}\text{Si}_y\text{O}_{12}$ compounds [228]). These have the general formula $\text{A}_x\text{M}_2(\text{XO}_4)_3$, where A is an alkali metal or alkaline earth, M is a transition metal or combination of transition metals, and X is P, As, Si, or S or a combination of these. M is octahedrally coordinated by oxygen, and X is tetrahedrally coordinated. All corners of the XO_4 tetrahedra are shared with MO_6 octahedra and vice versa; these link to form open channels in which the alkali or alkaline earth ions are located. There are also closely related three-dimensional framework structures with differing arrangements of corner-sharing polyhedra and distributions of alkali metal cations, such as the monoclinic $\text{Li}_3\text{Fe}_2(\text{PO}_4)_3$ shown in Fig. 13.

Transport of alkali metal ions through the tunnels in Nasicons can be extremely rapid, particularly at elevated temperatures, although the electronic conductivities are low. For these reasons, these materials were originally proposed for use as solid ionic conductors (e.g., to replace β'' alumina in high temperature Na/S batteries). In spite of their low electronic conductivities, researchers recognized that Nasicon structures with redox-active transition metals and related three-dimensional framework compounds could function as electrode materials as early as the late 1980s [229–231] and numerous materials were investigated [232, 233]. In many cases, the electrochemical properties are

Battery Cathodes. Figure 13

The structure of monoclinic $\text{Li}_3\text{Fe}_2(\text{PO}_4)_3$ looking down the unique axis. P is located in the blue tetrahedra, and Fe in the green octahedra. Li ions are represented as spheres

unsuitable for Li-ion batteries. For example, Li cannot be extracted from monoclinic $\text{Li}_3\text{Fe}_2(\text{PO}_4)_3$, only inserted, and the discharge occurs at a rather low voltage (2.8 V versus Li/Li^+). In contrast, up to two lithiums per formula unit can be extracted reversibly from monoclinic $\text{Li}_3\text{V}_2(\text{PO}_4)_3$, corresponding to a capacity of about 130 mAh/g at an average potential of 3.8 V [234–236]. Complex multiphasic behavior is exhibited upon redox, resulting in multiple plateaus in the discharge profile. In spite of significant volume changes upon lithium insertion and extraction, the material shows very good cycling behavior.

Fluorophosphates are relatively rare, but have recently been studied for Li-ion applications. The lithium in LiVPO_4F [237–239] can be extracted reversibly at a potential of about 4.2 V versus Li/Li^+ . Interestingly, lithium can also be inserted at about 1.8 V. Thus, a graphite-free lithium-ion battery can be built, using LiVPO_4F as both the anode and the cathode! $\text{Na}_3\text{V}_2(\text{PO}_4)_2\text{F}_3$ [240], $\text{Na}_2\text{FePO}_4\text{F}$ [241], and LiFePO_4F [242, 243] have also been investigated. The first two compounds were used as-is in electrochemical cells, and underwent ion exchange in situ. Although these cathodes eventually stabilize when used in lithium metal cell configurations and the cycling behavior is good, the presence of sodium in full cells with graphite anodes may disrupt the SEI layer and is therefore undesirable. Thus, these compounds will have to be ion-exchanged prior to use. In the case of LiFePO_4F , the investigators saw some evidence that a small amount of lithium could be extracted (with concomitant oxidation of Fe^{3+} to Fe^{4+}), but the main electrochemical reaction was insertion of lithium and reduction of Fe^{3+} to Fe^{2+} .

Other electroactive phosphorus-containing compounds include iron(III) hydroxyl phosphates with lipscombite or tavorite structures [244, 245], β - and ϵ - VOPO_4 [246–248], and LiVP_2O_7 [249]. Although the Nasicons, three-dimensional framework structures, and the aforementioned phosphates and diphosphates all have interesting electrochemical properties, most are not competitive with LiFePO_4 or the commercialized metal oxides for a variety of reasons. The iron-containing materials generally discharge at too low a voltage for use in Li-ion battery configurations and many have fairly low capacities. Some would need to be lithiated prior to use. The vanadium-containing

materials cycle well, and have sufficiently high voltages and capacities to ensure high energy density, but raise concerns about toxicity and environmental impact.

Interest has also recently been directed toward a family of silicates with the general composition Li_2MSiO_4 , where M is a divalent cation such as Fe^{2+} , Mn^{2+} , and Co^{2+} or a combination of these [250–257]. The chemical formula implies that it may be possible to extract two Li ions per transition metal unit, giving a very high theoretical specific capacity of about 330 mAh/g. These materials adopt structures in which Li, Si, and the transition metal ions all occupy tetrahedral sites in a distorted close-packed oxygen array. The particular polymorph obtained depends upon the nature of the transition metal as well as the temperature and method of preparation. In the β -polymorphs (low-temperature forms), the tetrahedra share only corners, and all point in the same direction. In γ -polymorphs (high temperature forms), triads of tetrahedra are arranged so that the central one points in the opposite direction and shares edges with the two outer tetrahedra. Numerous tetrahedral structures exist, with different ordering of the ions and varying degrees of distortion. Several different views of an electroactive β -polymorph (space group $\text{Pmn}2_1$) are shown in Fig. 14, which illustrates its quasi-layered nature. Accurate structure determination of these phases is complicated by the presence of impurities in many preparations and variations in synthetic procedures, which may lead to subtle structural differences [256, 258].

About one Li^+ per formula unit can be extracted from $\text{Li}_2\text{FeSiO}_4$ in electrochemical cells at low current densities and at 60°C [250, 251]. The initial extraction takes place at about 3.1 V versus Li/Li^+ , but subsequent discharges and charges occur at 2.8 V. This indicates that a structural change takes place, the exact nature of which is not entirely clear. After this initial change, however, relatively good cycling is observed, with an overall capacity of about 130 mAh/g (corresponding to somewhat less than 1 Li^+ per $\text{Li}_2\text{FeSiO}_4$). There is no experimental evidence that more than one Li^+ can be extracted, and first principle calculations indicate that it is not possible to do so at potentials compatible with conventional organic liquid electrolytes [259].

The differences between the potentials at which the first and second lithium ions can be extracted are much smaller when $\text{M}=\text{Mn}$, Co , or Ni in Li_2MSiO_4 than when it is Fe , however. As with the olivine system, the redox potentials for $\text{Li}_2\text{MnSiO}_4$ electrochemical processes (at least for extraction of the first lithium) are expected to be within the oxidative stability limits of organic electrolytes, while those of $\text{Li}_2\text{CoSiO}_4$ and $\text{Li}_2\text{NiSiO}_4$ are probably not. However the electrochemical behavior of $\text{Li}_2\text{MnSiO}_4$ appears to be much worse than that of $\text{Li}_2\text{FeSiO}_4$ [251, 254]. Belharaouk et al. [253] were able to achieve initial discharge capacities of about 135 mAh/g at room temperature, over a wide voltage range, by using carbon-coated submicron-sized particles, but this is still far less than predicted for complete extraction of all the lithium. Discharge capacities as high as about 250 mAh/g, however, can be obtained when

Battery Cathodes. Figure 14

Views of a β -polymorph of Li_2MSiO_4 looking down the a -axis (left), the b -axis (middle), and the c -axis (right). MO_4 (yellow) and SiO_4 (pink) tetrahedra alternate and connect to form layers through which lithium ions (green spheres) can diffuse

mixed metal compounds $\text{Li}_2\text{Mn}_x\text{Fe}_{1-x}\text{SiO}_4$ [252, 256] are used as cathodes in lithium cells. Unfortunately, the quality of the energy obtained is poor because the voltage profiles are steeply sloping over a range of about 4.5–1.0 V versus Li/Li^+ . At such low potentials, relatively little power can be obtained from the electrode. The extreme slope may be partly due to the severe kinetic and electronic limitations of the materials, leading to large over-potentials in lithium cells. If so, a combination of the carbon-coating and nanostructuring strategies used to improve the olivines may ameliorate the poor voltage characteristics and lead to new cathodes with nearly double the energy currently available.

Conversion Electrodes

A different class of electrode materials is based not upon insertion processes but on the displacement reactions of binary metal compounds [260, 261] (Eq. 4):

Conversion electrodes have long been used in primary systems (e.g., Li/CF_x batteries), but have only been proposed for use in rechargeable devices recently, when it was recognized that the reactions could be made reversible for nanoparticulate materials. While the specific capacities can be enormous, the voltage characteristics make most of these electrodes more suitable for use as anodes rather than as cathodes. A notable exception seems to be that of metal fluorides, which are electroactive anywhere from 2 to 4 V versus Li/Li^+ , depending on the identity of the metal, with specific capacities as high as 600 mAh/g. It is typical of conversion electrodes to exhibit significant hysteresis upon recharge, which may be intrinsic to the materials and processes. The mechanisms of conversion reactions are complex and involve bond breaking and considerable rearrangement, unlike that of insertion electrodes. The reassembly of the original phase upon recharge does not necessarily involve the same kinetic pathways and intermediates as the production of the elemental metal and LiF during discharge. Thus, it may not be possible to remove the hysteresis entirely either by engineering of devices or by improving the material properties to ensure faster rate capability. This property

has an adverse effect on the round-trip efficiencies, and may make conversion electrodes unsuitable for Li-ion batteries unless a solution can be found to this problem.

Future Directions

Because none of the cathode materials discussed above are ideal for every application, the search for new insertion electrodes continues. Batteries are relatively simple devices, but the simultaneous requirements for high energy density, long cycle life, safety, and low cost impose stringent restrictions upon the choices available for cathode materials. The highly successful example of LiFePO_4 has directed researchers toward the exploration of other poly-anionic compounds that may share its excellent thermal stability at high states of charge. It is now evident that nanostructuring and/or conductive coatings can overcome kinetic and electronic limitations, allowing materials that would once have been thought of as unsuitable for electrodes to be considered. Changes in the phase behavior of nanoparticulate materials (in comparison to the conventionally sized powders) can render compounds electroactive that, in bulk form, appear to be unpromising due to their insulating nature. The shortened diffusion distances for lithium in nanoparticles may enable high rate capability in powders that appear to have severe rate limitations when micron-sized or larger. While this allows the menu of potential cathodes to be greatly expanded, the concept of “going nano” should be approached with caution. It is most successful when it is applied to materials that undergo redox well within the electrolyte stability range, such as with LiFePO_4 . The increased surface area of nanoparticulate powders compared to conventionally sized materials exacerbates any tendency toward irreversible reaction with electrolytes. In addition to the very serious safety concerns this raises, the paradoxical result may be to lower rate capability due to the increased presence of resistive reaction layers on cathode particle surfaces [262]! Nano-sizing may also adversely impact practical specific energies because processing into electrodes becomes more difficult. It is often necessary, for example, to add more carbon to the composite cathode to ensure good electrical connectivity, but this contributes dead weight. High surface area particles also do not

pack well, leading to decreases in the tap densities and lower energy densities. Ensuring that nanoparticles are regularly shaped rather than irregularly can ameliorate these tendencies, however [263]. Another potentially useful approach is to synthesize mesoporous materials [264] in which the particles are micron-sized but contain pores of controlled sizes and distributions so as to maximize contact between the electrolyte and active material. This effectively shortens diffusion distances, while minimizing the tap density effects and maintaining the ease of electrode processing.

The use of nano metric or very thin coatings on cathode particle surfaces to improve the electronic conductivity of a material, to decrease dissolution, suppress oxygen loss, or to extend the operating voltage range is somewhat less problematic than simply nano-sizing cathode powders. In principle, this may allow using a wider variety of materials, including high-voltage/high-energy electrodes safely, without compromising cycle life or requiring the use of exotic electrolytes. Here the challenge is to identify and prepare coatings that prevent contact with electrolyte, yet allow the transport of lithium ions. They must also remain essentially defect-free over many cycles in which the cathode particles may undergo significant volume changes. A related concept is the preparation of “core-shell” or compositionally graded materials in which two or more compounds are combined in the same particle [265]. The core of the material can be a high-capacity material and the outer shell one that has lower energy but better thermal stability, for example. A difficulty is the tendency for the shell to become detached from the core if the volume changes upon cycling are not carefully matched. A compositionally graded material is less subject to these stresses, but more complex to prepare.

Researchers continue to look for materials that can deliver higher capacities and energies than those currently available. The layered-layered composite materials (i.e., the solid solutions between Li_2MnO_3 and $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ or $\text{LiNi}_x\text{Co}_{1-2x}\text{Mn}_x\text{O}_2$), which are very high capacity once they are activated in electrochemical cells, are a recent promising development. Cathodes that can undergo more than one oxidation state change per metal center reversibly could substantially increase the capacity of lithium-ion batteries. These include the Li_2MSiO_4 compounds and

conversion electrodes discussed above, but these require much more work before they can be envisioned for use in lithium-ion batteries.

The challenges presented by these new materials illustrate the delicate balance of performance characteristics, cost, and safety that the battery electrode designer must be able to meet. There is now renewed interest among researchers in lithium metal batteries, because of the very high energy densities that might be achieved. However, now instead of intercalation electrodes, developers are reconsidering the use of sulfur and air (oxygen) cathodes for lithium metal batteries intended for vehicles. The extremely high theoretical capacities of these materials (e.g., over 1,600 mAh/g for sulfur) in lithium batteries are certainly tantalizing, but the difficulties associated with their use have proven daunting. In the case of sulfur, LiS_x intermediates dissolve in the electrolyte solutions, eventually migrating to the lithium anode and precipitating as Li_2S . The development of the protected lithium electrode (PLE) by PolyPlus Battery Company (Berkeley, CA) has extended the cycle life significantly, and Li/S batteries are now used for some military applications. In PLEs, the lithium anode is covered by a thin dense protective film (e.g., a lithium-ion conducting ceramic such as Lisicon, a ceramic with the Nasicon structure), which not only prevents contact with soluble intermediates but also with the electrolyte. An interlayer between the lithium and the protective layer is also needed to prevent reduction of the latter. Thus, in principle, it is possible to operate lithium cells with a wide variety of electrolytes, including aqueous ones. A lithium/water battery has even been developed for niche applications, although it is intended for use only as a primary, at present.

While in principle it should be possible to operate a lithium/air battery using a PLE to prevent contact of lithium with adventitious water and CO_2 in the atmosphere, rechargeable systems have so far eluded success. The reduction of oxygen itself is somewhat sluggish, necessitating the use of a catalyst. The Li_2O_2 , which is the reaction product when nonaqueous electrolytes are used, precipitates out during discharge and eventually clogs the pores of the air electrode structure. While some researchers have claimed to have successfully recharged a lithium/air battery, the large hysteresis observed suggests that a side-reaction involving the

electrolyte is responsible for the charging behavior instead of reoxidation of Li_2O_2 to oxygen.

Ultimately, the success or failure of lithium/sulfur or air systems, however, hinges upon convincing demonstration of safe and reliable operation of the lithium anode over the many cycles required for applications requiring rechargeable devices.

Glossary

Battery efficiency Output energy/input energy for storage of electrical energy as chemical energy.

Electrolyte window Separation of electrolyte LUMO and HOMO energies of a liquid electrolyte and of conduction and valence bands of a solid electrolyte.

Fermi energy Electrochemical potential of a solid.

HOMO Highest occupied molecular orbital.

Insertion compound A host solid into which a working ion (guest) can be inserted/extracted reversibly over a solid-solution range.

LUMO Lowest unoccupied molecular orbital.

Polarization, $\eta = V_{OC} - V(q, I)$ Loss of battery voltage at a state of charge q due to resistance to ion transfer inside battery cell where an electronic current I is flowing outside of battery.

Rate of charge/discharge, nC Time, $(60/n)$ min, for complete discharge or charge of a battery or cell; it is also a measure of the current.

Redox couple Cation $M^{(m+1)}/M^{m+}$ mixed-valent energy applicable to localized-electron configurations.

SEI layer Solid/electrolyte interface (passivation) layer at an electrode having its Fermi energy outside the electrolyte window.

Separator A solid layer permeable to the working ion that separates anode from cathode to prevent electron transfer between them inside a battery cell.

Spin state Refers to spin of a redox couple, which may be reduced (low-spin state) from its free-ion value (high-spin state) by a ligand-field splitting of energies of atomic orbitals that is larger than the Hund intraatomic-exchange splitting of electron spins.

State of charge Amount of chemical energy in a battery or cell relative to the total energy available.

Tap density A measure of the volume density, which increases with compaction of the active electrode particles.

Working ion Ion carrying ionic current inside a battery cell.

Definition

The active materials of a battery are the chemically active components of the two electrodes of a cell and the electrolyte between them.

A battery consists of one or more electrochemical cells that convert into electrical energy the chemical energy stored in two separated electrodes, the anode and the cathode. Inside a cell, the two electrodes are kept apart by an inert separator that is permeable to a liquid electrolyte or by a solid electrolyte. The electrolyte allows transfer from the anode to the cathode of only the working cation, which carries the positive charge associated with the chemical reaction between the electrodes; the electrolyte and separator force the electrons of the reaction to flow outside the battery where they can be stopped (open circuit) or discharged from the anode to the cathode through a load where

they do work. In a rechargeable battery, the chemical energy can be restored by the application of a reverse charging current. The active materials determine such parameters as the electric-power capability of a battery, its energy density, its calendar and cycle life, its cost, and its safety. Each battery application has a different set of requirements. Tailoring of the active materials to the demands of a particular application is an ongoing process. These applications range from the powering of heart pacemakers to portable electronic devices to electric vehicles to electrical-energy storage for the grid. The active materials used in batteries for some of these different applications are discussed.

Introduction

The conversion of chemical energy to electricity was first demonstrated in 1800 by Volta, who constructed a battery – the *voltaic pile* – from alternating plates of silver and zinc separated by a cloth soaked in a salt solution. In 1806, Davy used the electricity from a voltaic pile to convert electrical energy into chemical energy by separating electrochemically alkali metals from their hydroxides. The electrochemical cell was invented in 1836 by Daniell, who immersed Zn in an aqueous $ZnSO_4$ solution and copper in a $CuSO_4$ solution in separate tubes; the two tubes were joined by a salt bridge containing a porous glass frit. This cell was called a *galvanic cell* in memory of Galvani, who had discovered in the 1790s that two different metals and a salt solution could cause muscle contractions in a frog's leg. Galvanic cells were developed to supply electricity before electric generators were available. The gifted experimentalist, Michael Faraday, began his career as an apprentice in Davy's laboratory; he later went on to lay the foundations for the science of electrochemistry and the development of the modern battery. It was Faraday who was to refer to the two different metals of a voltaic pile and of a galvanic cell as electrodes; the reductant was called the anode and the oxidant the cathode. The salt solution connecting the two electrodes by an ionic current was the electrolyte. Negatively charged ions are referred to as anions and positively charged ions are referred to as cations because they are attracted, respectively, to the anode and the cathode when electrons flow from the anode to the cathode.

Batteries

A *battery* consists of one or more electrically connected *electrochemical cells* that store chemical energy in their two *electrodes*, the *anode* and the *cathode*; the battery converts the chemical energy into electrical energy on *discharge*. The electric output of a battery is a *discharge current* I at a voltage V to give an electric-power output $P = IV$. The power capability is expressed as *specific* or *gravimetric power* in watts per kilogram (W/kg) or *volumetric power density* in watts per liter (W/L). The *energy density* of a battery is the amount of *electrical energy* QV that is available from a fully charged battery per unit weight or volume; it is expressed as *specific* or *gravimetric energy* in watt-hours per kilogram (Wh/kg) or as *volumetric energy density* in watt-hours per liter (Wh/L). Q is the total charge transported by I over the time Δt of a complete discharge

$$Q = \int_0^{\Delta t} I dt = \int_0^Q (dq/dt) dt \quad (1)$$

and Q/weight (Ah/kg or mAh/g) is the *capacity* of the battery. The voltage of a battery can be increased by connecting individual electrochemical cells in series; the current per cell for a given battery current can be decreased and therefore the time for a full discharge can be increased by connecting cells in parallel. The larger the voltage and capacity of an individual cell, the fewer the cells in the battery.

A *primary battery* is discarded after providing electrical power until its chemical energy is exhausted. A *secondary battery*, also called a *rechargeable battery* or an *accumulator*, can have its spent chemical energy restored by the application of a *charging current* in a direction opposite to that of the discharge current. The *cycle life* of a secondary battery is the number of discharge/charge cycles it can support before losing 20% of its capacity. The energy loss per cycle is the difference between the electric energy used to charge the battery and that gained on discharge; the electrical energy gained on discharge divided by the electrical energy spent on charge is the *efficiency* of a secondary battery for storage of electrical energy.

Figure 1 illustrates schematically the components of an individual electrochemical cell. The *anode* is a reductant and the *cathode* is an *oxidant*. Inside the

Battery Components, Active Materials for. Figure 1 Schematic showing components of $\text{LiC}_6/\text{Li}_{1-x}\text{CoO}_2$ cell. Internal Li^+ -ion and external electronic (e^-) currents I_i and I are shown for discharge with switch closed. The SEI passivation layer is formed because the energy E_{FA} of the LiC_6 anode is higher than the LUMO of the carbonate electrolyte (see Fig. 3)

cell, the two electrodes are kept apart by a physical barrier, a *separator*, that prevents any electron transfer between them inside the cell. However, the two electrodes are connected electrically inside the cell by an *electrolyte* that conducts a *working ion* and is an electronic insulator. A liquid electrolyte permeates a chemically inactive, porous separator; a solid electrolyte also acts as a separator. The working ion is normally a cation: H^+ , Li^+ , or Na^+ . Chemical reaction between the two electrodes of a cell involves both electron and working-ion transfer between the electrodes. The electrolyte forces the electrons to flow outside the cell while allowing the working ion to be transported inside the cell. Therefore, a battery has a *negative terminal* that collects electrons via a *current collector* from all the cell anodes for delivery to an external circuit and a *positive terminal* that receives electrons from the external circuit and delivers them via a current collector to all the cell cathodes during a battery discharge.

External connection of the battery terminals allows an electronic discharge current I to pass through an external load of resistance R_L , where it does work, to the cathode where it neutralizes the ionic current I_i inside the battery. Thus, on discharge the battery transforms its chemical energy into electrical energy at the load. The much higher electronic conductivity σ_e compared to the working-ion conductivity σ_i means that a cell is

Battery Components, Active Materials for. Figure 2 Voltage levels in the various sections of a cell at open circuit. The double layers at the anode and the cathode have different structures and compositions

fabricated with a small thickness/area ratio. Disconnection of the two battery terminals stops not only the external discharge current, but also the internal ionic current since, without charge neutralization, an internal electric field between the cell electrodes is built up to stop further flow of the working ion. This electric field is expressed as a voltage between the terminals of a cell at open circuit, the *open-circuit voltage* V_{oc} , with a positive charge at the cathodic positive terminal and a negative charge at the anodic negative terminal. Mobile ions in the electrolyte form *electrical double layers* at the surfaces of the electrodes to neutralize the electrode charge, and the voltage drop inside the cell is across the double layers, Fig. 2.

This entry describes strategies used by the chemists to identify appropriate active materials, electrodes and electrolyte, for the individual electrochemical cells of a battery.

Fundamental Constraints

Maintaining Electrode–Electrolyte Contact

Ion transfer across the electrode/electrolyte interfaces requires retention of a good electrode–electrolyte contact during discharge and charge. Since ion and electron transfers between the electrodes change the volumes of the electrodes, it is advantageous to have

a liquid or polymer electrolyte contacting solid crystalline electrodes; a solid electrolyte is needed to keep the electrodes apart if one or both of the electrodes is a liquid or a gas.

Electrolyte Window

The *window* of a liquid electrolyte is the energy gap E_g between its lowest unoccupied molecular orbital (LUMO) and its highest occupied molecular orbital (HOMO). The window of a solid electrolyte is the energy gap E_g between the bottom of the empty electronic conduction band, E_c , and the top of the filled electronic valence band, E_v . Figure 3 illustrates how the window of an electrolyte constrains the V_{oc} of a cell.

Figure 3a shows the case of solid electrodes having anode and cathode Fermi energies E_{FA} and E_{FC} in their electronically conductive state. An E_{FA} or E_{FC} may lie in a partially filled conduction band or in a mixed-valent redox couple. An E_{FA} above the electrolyte LUMO will reduce the electrolyte and an E_{FC} below the electrolyte HOMO will oxidize the electrolyte. Therefore, thermodynamic stability restricts the open-circuit voltage to

$$eV_{oc} = E_{FA} - E_{FC} \leq E_g \quad (2)$$

where e is the magnitude of the charge of an electron. However, charge transfer at an electrode/electrolyte interface may create a double layer and/or a passivation layer that blocks a subsequent ionic transfer at open circuit to stop any further electrolyte reduction or oxidation and therefore to give a *kinetic stability* for a limited $(eV_{oc} - E_g) > 0$. A passivation layer is referred to as a *solid-electrolyte interphase* (SEI); it should not block ion or electron transfer under closed-circuit conditions.

Solid electrolytes, Fig. 3b, are chosen to have a window $E_g > eV_{oc}$.

Ionic Conductivity

Kinetic limitations on the rate of working-ion transfer between electrodes cause the cell voltage V to drop relative to V_{oc} . The voltage drop

$$\eta(q, I) = V_{oc} - V \quad (3)$$

is called the *polarization* or the *overvoltage*; q is the state of charge. The polarization is due to the resistance to ionic motion inside the cell.

Battery Components, Active Materials for. Figure 3

Definition of the electrolyte window E_g for (a) liquid and (b) solid electrolytes. The E_{FA} and/or E_{FC} of solid electrolytes may lie in either a band of one-electron states as in (a) or a multielectron redox couple as in (b); for liquid electrodes, they lie in a mixed-valence redox couple

Ions move diffusively. Therefore, the ionic conductivity is given by

$$\sigma_i = (nq^2/kT)D_i \sim Nc(1-c)\exp(-\Delta H_m/kT) \quad (4)$$

where $n = cN$ is the density of carriers of charge q ; $D_i = D_0 \exp(-\Delta G_m/kT)$ is the ionic diffusion coefficient containing a Gibbs free energy $\Delta G_m = \Delta H_m - T\Delta S_m$ for an ion to move from one position to another. The motional enthalpy ΔH_m is an activation energy for ion motion, and $(1-c)$ is the fraction of sites that are empty into which ions can move.

In a strong acidic or alkaline aqueous electrolyte, $n = cN$ is large and ΔH_m is small so long as the water molecules are free to rotate as in a liquid; the H^+ ions hop within hydrogen bonds, but molecular rotation is needed to subsequently reorient the hydrogen to a new bond direction (Grotthus motion). In a liquid aqueous electrolyte, the H^+ -ion conductivities are generally $\sigma_H \approx 1$ S/cm at 20°C. However, the window of an aqueous electrolyte is only 1.23 eV, which has led to consideration of nonaqueous electrolytes. Since H^+

ions are not mobile in nonaqueous liquid electrolytes, the Li^+ ion is normally used in these electrolytes. Few organic solvents dissolve a sufficient concentration of lithium salts with good separation of the Li^+ ions from the anion of the salt. The Li^+ -ion conductivities in the best nonaqueous liquid electrolytes are $10^{-3} < \sigma_{Li} < 10^{-2}$ S/cm at 20°C.

Solid cathodes of secondary-battery cells are *insertion compounds*. An insertion compound has a *host* crystalline structure into which a *guest* working ion can be inserted/extracted reversibly into/from its interstitial space while the ionic charge is being neutralized by reduction/oxidation of the host structure with electrons coming from/sent to the external circuit. These electrodes are mixed ionic/electronic conductors. During an insertion or extraction reaction, the essential architecture of the host structure remains intact throughout the process, but two types of insertion reaction need to be distinguished: (1) a single-phase solid-solution reaction between the guest and the host; (2) a two-phase reaction. A first-order transition

between two phases results in the coexistence of the two phases; a first-order transition may not be reversible, but where the host undergoes an ion-displacement transition that separates a phase rich in the working ion from one that is poor in the working ion, the two-phase reaction can be reversible. In a single-phase solid-solution reaction, the output voltage V of the cell decreases monotonically with its state of charge as is illustrated schematically in Fig. 4a. The *state of charge* of a cell refers to the fraction of the full-charge chemical energy existing in a partially charged cell. Where the host structure undergoes a first-order structural change during discharge, the output voltage V of the cell is independent of the state of charge over the two-phase region as is illustrated in Fig. 4b. This behavior follows from the Gibbs phase rule, which states that the number of thermodynamic parameters that are free to vary is

$$F = C - P + 2 \quad (5)$$

where P is the number of coexisting phases and C is the number of components, guest and host, taking part in the reaction. Where two phases coexist, $C = P$ and $F = 2$. Since temperature and pressure are specified, there is

Battery Components, Active Materials for. Figure 4 Schematic profiles for (a) a solid-solution insertion reaction and (b) a two-phase insertion reaction showing the polarization $\eta = V_{OC} - V$. Note: Two-phase reactions retain the higher voltage found at the onset of the two-phase region

no degree of freedom left, so other parameters such as voltage have to be constants. In an insertion reaction, the host interstitial space into which the working ion can be inserted may be 1D, 2D, or 3D (D = dimensional) depending on the host structure.

In Fig. 4a, three ion-transfer processes are distinguishable: (1) an *activation polarization* due to the energy ΔH_m required to transfer ions across the electrode/electrolyte interfaces, (2) a change in $E_{FA} - E_{FC}$ and (3) an end-of-life *concentration polarization*. The slope in region (2) of a similar $V(q)$ vs. I curve gives the *ohmic polarization*. The activation polarization is manifest on the initiation of discharge; the ohmic polarization is manifest by the slope of the $V(I)$ profile in mid-discharge. At the end of life, either the concentration of working ions reaching the cathode is depleted and/or the concentration $(1-c)N$ of the cathode acceptor sites at the electrolyte/electrode interface is depleted to where the ionic diffusion current is no longer able to keep up with a fixed discharge current I . The increase in η causes a decrease in V at the end of life, and this decrease occurs at a larger state of charge the higher is I and, from Eq. 4, the lower is the temperature T . The end-of-life drop-off in V is also referred to as the *diffusion-limited* regime of the $V(t)$ profile. The loss of capacity at higher I and lower T is *reversible*; capacity is restored at lower discharge currents I and higher temperatures T where the working-ion profile across the electrolyte/electrode interface approaches more closely the equilibrium profile. Thus, the reversible Q of Eq. (1) decreases with increasing I ; $Q = Q(I)$. Clearly, a fast diffusion of the working ion not only in the electrolyte, but also in any insertion-compound electrode is needed for a secondary power battery.

Energy Density

The specific energy QV/weight of a cell depends not only on the voltage V of the cell, but also on the total charge Q per kilogram that is transported between the electrodes. In order to achieve a high cell voltage, the E_{FA} of the anode and the E_{FC} of the cathode need to be matched to the LUMO and the HOMO, respectively, of an electrolyte with a large window E_g between its LUMO and HOMO. In a secondary battery, Q is the total charge that is transported reversibly between the electrodes. In a secondary battery in which the cells

are assembled in the discharged state, Q is limited to the number and charge of working ions that can be extracted reversibly from the cathode host. However, where the anode develops a non-blocking SEI layer, Li^+ ions are trapped irreversibly in the SEI layer during the initial charge, which reduces the capacity available from the cathode on subsequent charge/discharge cycles. To eliminate this loss of cathode capacity, it would be necessary to form the SEI layer on the anode before assembling the cells of a battery.

In addition to formation of an SEI layer on the anode, chemical reactions between the cathode and the electrolyte or within the cathode can deplete the amount of active cathode material. These reactions introduce an *irreversible* capacity loss that is expressed as a *capacity fading* with the number of charge/discharge cycles. The *cycle life* of a cell is the number of discharge/charge cycles a cell can undergo without too great an irreversible capacity loss to be useful; the *service life* of a cell is the length of time over which the cell retains more than 80% of its capacity. The service life depends on the cycle life, that is, the cell use as well as on the age of the cell.

Morphology

In order to minimize the reversible capacity loss at higher discharge/charge currents, solid electrodes are made porous so as to maximize the electrode/electrolyte interface area per unit planar area of the electrode. Solid porous electrodes are commonly a complex composite of the active material in the form of small particles coexisting with and contacting a current-passing additive such as carbon, metal particles, or a conductive polymer; the conductive additive percolates through the composite mass to connect electronically the active particles to one another and to the electrode current collector. This composite mass is commonly held together by a chemically inactive binder such as Teflon. Typically, such a composite electrode has about 30% porosity percolating through it so as to allow impregnation of the pores by a liquid electrolyte in order to have the electrolyte contact every active particle. The resulting electrode/electrolyte interface area is complex, and the ionic currents within the composite electrode are tortuous. Modeling the current flows within an electrode as well as the composite

morphology has become an important tool in the design of a composite electrode and of the distribution of primary currents in the metallic current collectors.

Heat

The net useful energy released for a given chemical reaction between the electrodes is the enthalpy ΔH of the Gibbs free energy

$$\Delta G = \Delta H - T\Delta S \quad (6)$$

where $T\Delta S$ is the heat associated with the entropy change ΔS of the reaction at an absolute temperature T . For a fixed T , this heat is reversible, that is, it is exothermic on discharge and endothermic on charge or *vice versa*. In electrical terms,

$$\Delta S = nFdV/dT \quad (7)$$

where n is the number of electrons per mole of reactants participating in the discharge reaction and F is the Faraday constant, that is, the amount of charge transferred when one equivalent weight of mass reacts. From Eqs. 6 and 7, the reversible heat on discharge is $nFT(dV/dT)$, which may be positive or negative, exothermic or endothermic. In addition, the internal resistance R_b of a cell creates heat I^2R_b that must be dissipated. *Thermal runaway* occurs if the internal heat causes an electrode reaction with the electrolyte to become self-sustaining, the reaction entering an autocatalytic mode. This situation is responsible for fires associated with battery operations, and an internal electronic short circuit between the electrodes occasioned by dendrite growth from an anode across the electrolyte to the cathode with repeated cycling can trigger such an event where the electrolyte is flammable.

Cost

Cost as well as safety, capacity, and power capability are constraints on any commercial device. Lower cost requires not only low-cost, nontoxic materials, and simple battery-stack management, but also a long service life, ease of manufacture, and a minimization of the number of cells to achieve a specified voltage and discharge time. Safety of a secondary battery at an acceptable cost favors either a nonflammable electrolyte or a solid-electrolyte separator that blocks

short-circuiting from any dendrite formation on a solid anode where dendrite formation threatens short-circuiting of cells on repeated cycling. A long service life requires elimination of irreversible chemical reactions within the individual cells.

The cost and service life of secondary batteries for electric vehicles must compete against the cost and service life of the internal combustion engine. In their favor is elimination of the cost to the environment of distributed emissions of the greenhouse gas CO₂; and if charging of the battery of the electric vehicle can be done with wind or radiant solar energy, all CO₂ emissions associated with the vehicle can be eliminated.

Electrode Reactions

Primary batteries [1] having liquid electrolytes generally use a solution or a solution-precipitation reaction of an element at the anode and a displacement or insertion reaction at the cathode. Most secondary batteries use insertion reactions at a solid cathode and may also use insertion reactions at the anode.

Some common elemental solution or solution-precipitation reactions are:

The E_{FA} of Li⁰ lies above the LUMO of a nonaqueous liquid-carbonate electrolyte containing a lithium salt. Although a non-blocking SEI passivation layer is created at the surface, lithium is not plated back uniformly during a charge; it forms a rough, mossy surface that, on repeated discharge/charge cycles, develops dendrites that can grow across the electrolyte to contact the cathode. Therefore, with a liquid electrolyte Li⁰ is only used as an anode in a primary battery or in half-cells used to test the performance of candidate cathode materials for secondary batteries. However, it may be used in a secondary cell having a solid Li⁺-ion electrolyte that blocks dendrite growth across it and is not reduced on contact with a dendrite.

The E_{FA} of Zn⁰ lies 0.76 eV above the 2H⁺/H₂ LUMO of an aqueous electrolyte, which has previously prohibited its use in a secondary battery. However, it is used successfully as the anode of a primary cell having either an HCl acidic or KOH alkaline electrolyte. The Cd²⁺/Cd⁰ couple at 0.40 eV above the 2H⁺/H₂ couple is better matched to the aqueous LUMO, so Cd has been the preferred anode for a secondary alkaline battery with a KOH electrolyte. A lower electrochemical potential of an alkaline versus an acidic electrolyte allows the double layer in an alkaline electrolyte to lower the E_{FA} of Cd to below the 2H⁺/H₂O LUMO. The Pb²⁺/Pb⁰ couple is only 0.13 eV above 2H⁺/H₂, so it provides a reversible anode reaction in a sulfuric-acid electrolyte. In all cases with aqueous electrolytes, the anode-electrolyte reaction releases mobile working H⁺ ions to react with the cathode.

In a displacement reaction, the working ion displaces a cation of the electrode as is illustrated by the cathodic discharge reaction

Normally, such a first-order reaction is not easily reversed, and to date cathodes undergoing such a reaction are only found in primary batteries. However, they represent a Q corresponding to two electrons per electrode cation to give a large capacity. Although displacement reactions that leave a host framework intact may be reversible, for example,

the associated volume changes have made these reactions impractical unless they are buffered by an amorphous carbon matrix.

In a reversible insertion reaction, the working ion is inserted as a guest into a host structure forming either a solid solution in a single-phase reaction or two phases in a first-order reaction in which ionic displacements of the host segregate the electrode into guest-rich and guest-poor phases. For example, two anode reactions are the single-phase reaction of a metal hydride MH

and the lithiated graphite two-phase reaction

in which graphene sheets are shifted in stages relative to one another on Li insertion (Fig. 9). In anodes, the guest is inserted on charge and extracted on discharge. As a cathode, the guest is inserted on discharge and extracted on charge.

Primary Batteries

Zinc–Manganese Batteries

Zinc–manganese batteries [1] dominate the primary-battery market. These batteries are of two types depending on the pH of their aqueous electrolyte. Each uses a carbon-MnO₂ cathode; the carbon provides electronic conductivity. The MnO₂ is best

prepared as αMnO₂ or γMnO₂, which have structures, Fig. 5, with 1D channels into which H⁺ ions can be inserted. The Leclanché cell, Zn/HCl/MnO₂, is acidic, and the Zn anode undergoes a Zn-solution reaction; Zn²⁺ ions enter a ZnCl₂ + NH₄Cl salt solution to displace 2H⁺ ions to the cathode. In the alkaline cell, Zn/KOH/MnO₂, the Zn anode reacts with the aqueous electrolyte to form Zn(OH)₂ + 2H⁺; the Zn(OH)₂ subsequently transforms to ZnO↓ + H₂O. As shown in Fig. 6, the discharge voltage of a zinc–manganese battery exhibits two ranges, one corresponding to a single-phase solid-solution reaction

Battery Components, Active Materials for. Figure 5

Structures of (a) α – MnO₂, (b) γ – MnO₂, (c) Ni-exchanged cryptomelane. Octahedral sites of MnO₂ share edges along the c-axis. H⁺ ions are inserted into the 1 × 2 tunnels

Battery Components, Active Materials for. Figure 6 Discharge voltage profile of the $\text{MnO}_{2-x}(\text{OH})_x$ cathode of a Zn/ MnO_2 primary battery showing solid-solution (one-phase) and two-phase compositional ranges

and the other to a two-phase reaction that is irreversible. An octahedral-site Mn(III) ion has a twofold orbital degeneracy, and at a sufficient concentration of Mn(III) ions, a cooperative site distortion to remove the degeneracy introduces a first-order displacive transition of the host structure. The Mn(III)-rich phase at the surface undergoes a disproportionation reaction: $2 \text{Mn(III)} = \text{Mn(II)} + \text{Mn(IV)}$ that is followed by an *irreversible* dissolution of Mn(II) into the electrolyte. The better match of the E_{FA} of Zn^0 to the $2\text{H}^+/\text{H}_2\text{O}$ LUMO of the KOH electrolyte makes the alkaline cell more reliable and gives it a better performance at higher discharge rates. However, in the discharge reaction, a mole of H_2O per two moles of MnO_2 is consumed, which increases the impedance of the cell where the amount of electrolyte has been minimized to maximize the cell capacity. Ni-exchanged cryptomelane, Fig. 5c, alleviates this problem.

With 1D tunnels in the MnO_2 cathode, it is critical to remove impurities and structural stacking faults that would block a tunnel. Moreover, since the $\text{Zn}^0/\text{Zn}^{2+}$ couple lies above the $2\text{H}^+/\text{H}_2$ LUMO of the electrolyte, the Zn anode of the alkaline cell consists of Zn particles of selected size bound with the KOH electrolyte in a stabilizing gelling agent to suppress H_2 evolution. The selection of the gelling agent and the size of the Zn particles are critical. The gelling agent creates

a passivating SEI layer on the Zn to inhibit it from reducing the water at open circuit:

Zinc–Air and Silver–Zinc Batteries

The alkaline zinc–air battery has the highest energy density of all aqueous batteries since only the Zn-powder anode is contained in the cell; the other reactant, oxygen, is available from the surrounding air. The capacity of a cell is dictated by the amount of fine Zn powder that is available for discharge. Nevertheless, a light cathode structure is present; it consists of a porous carbon or nickel mesh containing both the liquid electrolyte to convey H^+ ions and MnO_2 or other particles as catalyst in the pores. Gaseous O_2 is given access to the porous carbon where it penetrates the pores to be reduced on the MnO_2 at a triple-phase boundary (TPB) by the reaction

However, the oxygen–reduction reaction Eq. 15 forms an intermediate peroxide:

and breakdown of the peroxide H_2O_2 and/or its radical O_2H^- is rate-limiting. These cells are available in sizes small enough to fit into the ear to power a hearing aid.

The silver–zinc battery also uses a KOH alkaline electrolyte. In this battery, the cathode undergoes the displacement reaction

This battery is primarily used in button cells for small portable devices such as watches.

Lithium Primary Batteries

Primary lithium cells use a lithium-metal anode and a nonaqueous electrolyte having a larger window than the 1.23 eV of an aqueous electrolyte. Both liquid and solid Li^+ -ion electrolytes can be used.

Liquid Electrolytes. The carbonates dissolve a fair concentration of lithium salts, normally LiClO_4 or LiSO_3CF_3 in propylene carbonate-dimethyl ether in

primary cells. Since the Li^0/Li^+ couple lies about 1 eV above the LUMO of the carbonate, dimethyl ether is added to react with the Li^0 to form a passivating SEI layer. With a passivating layer on the Lithium anode and an electrolyte window $E_g \approx 3.5$ eV, cell voltages of 4.0 V or higher are possible. With a higher voltage V , the lithium primary batteries provide a larger energy density, but Li^+ -ion transport across the SEI layer and a σ_{Li} in the nonaqueous electrolyte significantly lower than the σ_{H} in a strong acidic or alkaline aqueous electrolyte reduces the rate capability of a Lithium primary battery at 20°C. The solid-cathode insertion compounds CF_x and MnO_2 are thermodynamically stable and provide a long shelf life; Li/CF_x and Li/MnO_2 batteries have a $V = 3.0$ V and are designed for relatively low-rate applications.

The FeS_2 cathode of a Li/FeS_2 battery undergoes a two-step displacement reaction

in which an amorphous Li_2FeS_2 is first formed by the breaking of the disulfide $(\text{S}_2)^{2-}$ ions of FeS_2 . This battery only provides $V = 1.6$ V in the first step, but at higher temperatures it gives a high-rate performance superior to that of the alkaline Zn/MnO_2 cells.

The Li/I_2 cell is used preferably for implanted heart pacemakers; the di-iodine bond is broken at $V = 2.7$ V in the cathode reaction

Solid Electrolytes. A *protected Lithium anode* is under development for both primary and secondary batteries that promise much larger capacities. This strategy is illustrated by the $\text{Li}/\text{seawater}$ primary battery in which a Lithium anode is immersed in a nonaqueous electrolyte, the *anolyte*, that is separated from seawater contacting a cathode current collector by a Li^+ -ion solid-electrolyte separator. The seawater acts as a liquid cathode. Except for contact with a negative post, the Lithium anode and its anolyte are sealed in a compartment containing a Li^+ -ion solid-electrolyte wall that interfaces the seawater. The anolyte is chemically stable to both the Lithium and the solid electrolyte; the solid electrolyte must not be reduced on contact with the Li^0 anode. Moreover, either the seal or the compartment must be compliant to allow for the

change in volume of the Lithium on discharge. The seawater is not contained in an *open cell*; it is contained within a battery in a *closed cell*. The Li^+ ions from the anode react with water at the cathode current collector:

to give a constant voltage $V = 2.7$ V. The efficiency of a $\text{Li}/\text{seawater}$ secondary cell is not good, but other liquid cathodes, for example, $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$ in water, offer a more efficient electrical-energy storage than the seawater cathode and, with a solid electrolyte, permit a flow through of only the liquid cathode (see last section for flow-through rechargeable batteries).

Secondary Batteries with Aqueous Electrolytes

The *lead-acid battery* $\text{Pb}/\text{H}_2\text{SO}_4/\text{PbO}_2$ [1] provides a fast cell discharge at 2.0 V, it is relatively low-cost, and 98% of the batteries used in the USA are recycled. This battery has dominated the market for rechargeable batteries, but Pb is heavy and the practical energy density of the battery is only about 25% of its limited theoretical energy density (Wh/kg). Therefore, other secondary batteries are used for handheld devices and contend for the electric-vehicle market.

The Pb anode is matched to the $2\text{H}^+/\text{H}_2\text{O}$ LUMO of the aqueous H_2SO_4 electrolyte; during discharge, the Pb^{2+} ion forms PbSO_4 on entering the electrolyte to displace 2H^+ to the PbO_2 cathode. On reduction of the PbO_2 by electrons from the anode, H^+ ions are inserted into the PbO_2 to form $\text{PbO}_{2-x}(\text{OH})_x$. A kinetic stability impedes reaction of the reduced PbO_2 with the electrolyte, but electrons introduced into the Pb-6s band disproportionate into electron-rich $\text{Pb}(\text{OH})_2$ regions within the PbO_2 matrix

followed by a slow reaction

At open circuit, electrode reactions that charge the electrodes lead to a slow oxidation of the electrolyte with H_2 evolution at the anode and O_2 evolution at the cathode. These reactions represent an irreversible *self-discharge*. Once the electrolyte is introduced, the battery has a poor shelf life. Under development

are acidic aqueous electrolytes in which Pb(II) is soluble rather than condensing into the solid PbSO_4 . This development of the lead–acid cell promises a flow battery not requiring a separation membrane. The separation membrane of redox-flow batteries (see last section) remains a challenging problem for the aqueous redox-flow technology.

The *cadmium–nickel* cell, $\text{Cd}/\text{KOH}/\text{NiOOH}$, has its Cd anode and $\text{NiO}_{1-x}(\text{OH})_{1+x}$, $0 \leq x \leq 1$, cathode well-matched to the LUMO and the HOMO of the alkaline KOH electrolyte; the small, sealed cell gives a fast discharge and charge at a discharge voltage of 1.2 V. Like the Pb anode of the lead–acid battery, the Cd anode undergoes a solution-precipitation reaction in which Cd^{2+} reacts with the water of the electrolyte, Eq. 4, to form reversibly solid $\text{Cd}(\text{OH})_2$ and displace 2H^+ ions to the cathode. The cathode is the layered, monoclinic β -NiOOH of Fig. 7; it converts to hexagonal β -Ni(OH) $_2$ in a two-phase reaction on insertion of H^+ to give a plateau in the $V(x)$ discharge curve at 1.2 V versus $\text{Cd}/\text{Cd}(\text{OH})_2$. In β -NiOOH, the oxygen stacking along the c -axis within a unit cell is ABCA, Fig. 7;

Battery Components, Active Materials for. Figure 7 Layered structure of monoclinic β – NiOOH

the H^+ ions are located preferentially in the trigonal-prismatic sites between A-A stackings. Overcharging introduces water into the H-depleted galleries to give γ -NiOOH· $\gamma\text{H}_2\text{O}$. Best performance of the β -NiOOH- β -Ni(OH) $_2$ cathode is found with small particles having a large defect content. The gelatinous $\text{Cd}(\text{OH})_2$ remains close to the anode; and during charge, the $\text{Cd}(\text{OH})_2$ at the anode reverts to $\text{Cd} + \text{H}_2\text{O}$ as the cathode releases 2H^+ per Cd^{2+} ion to the electrolyte. At the end of charge, all the Cd^{2+} ions are reduced back to Cd and all the nickel is present as Ni(III). The Ni(IV)/Ni(III) couple cannot be accessed with a further increase in the charging voltage; instead, the electrolyte is oxidized:

This cell was the first rechargeable battery to be used in handheld devices.

With a suitable gelling agent to passivate carefully sized Zn particles, a $\text{Zn}/\text{KOH}/\text{NiOOH}$ secondary battery may be marketed.

The *metal hydride–nickel cell*, $\text{MH}_x/\text{KOH}/\text{NiOOH}$, also makes use of the NiOOH cathode; it replaces the Cd anode with a metal hydride, MH_x insertion alloy having its Fermi energy E_{FA} , like that of Cd, well-matched to the LUMO of the aqueous KOH electrolyte. However, the H^+ -ion diffusivity in the hydride is slower than that in the gelatinous $\text{Cd}(\text{OH})_2$, so it has a poorer rate capability at lower temperatures. On the other hand, it eliminates the heavy, toxic Cd to give a higher energy density (Wh/kg) and provides a safe power source for electric vehicles. However, a $\text{Zn}/\text{KOH}/\text{NiOOH}$ cell of good cycle life may prove competitive.

Nonaqueous Electrolytes for Li-Ion Secondary Batteries

The demand for a rechargeable battery with a greater specific energy requires a higher output voltage and therefore an electrolyte with a larger window E_g between its LUMO and HOMO than the 1.23 eV of an aqueous electrolyte. Since H^+ ions are not mobile over an appreciable temperature range above and below 20°C in the absence of water, the Li^+ and Na^+ ions are the next logical candidates for the working ion.

Early work with Na^+ ions concentrated on solid electrolytes. Although solid electrolytes have a large window, they do not retain a large-area interface with a solid electrode that changes its volume significantly with the state of charge of the battery. Although all solid-state microbatteries are made, a solid electrolyte preferably contacts a liquid, either a liquid electrode or a liquid electrolyte. The sodium–sulfur battery uses liquid electrodes and operates above 300°C [2]. On the other hand, a composite electrolyte having a solid-electrolyte separator and different liquid electrolytes either side, as in the Li/seawater primary battery, can provide a feasible room-temperature secondary battery [3]. For example, the Li^+ -ion solid-electrolyte $\text{Li}_{1.3}\text{Ti}_{1.7}\text{Al}_{0.3}(\text{PO}_4)_3$ with the framework structure of hexagonal $\text{Fe}_2(\text{SO}_4)_3$, Fig. 8, can have interstitial Li giving $\sigma_{\text{Li}} > 10^{-4}$ S/cm at 20°C [4]. Rechargeable batteries based on this strategy are now being investigated. However, this commercially available inorganic solid electrolyte contains Ti(IV), which is too easily reduced. Another solid electrolyte with a $\sigma_{\text{Li}} > 10^{-4}$ S/cm needs to be identified.

A solid polymer electrolyte can retain contact over a large surface area of a solid electrode provided the changes in electrode volume with state of charge of a cell are modest. Polyethylene oxides (PEOs) containing a lithium salt are low-cost, nontoxic,

Li^+ -ion electrolytes with good chemical stability [5], but a $\sigma_{\text{Li}} < 10^{-5}$ S/cm at 20°C is too low for a power battery and the HOMO versus Lithium is below 4.0 V. The introduction of the oxide particles Al_2O_3 , TiO_2 , SiO_2 , or ZrO_2 creates a more amorphous polymer matrix by inhibiting chain crystallization and attracting Li^+ from its salt; the result is an enhanced σ_{Li} and Li^+ -ion transference number $t = \sigma_{\text{Li}}/\sigma$, where σ is the total anion plus Li^+ -ion conductivity; but σ_{Li} is still not comparable to that of the best liquid electrolytes, [6]. Therefore, most attention has been given to Li^+ -ion batteries containing liquid electrolytes.

The most widely used liquid electrolytes consist of Lithium salts dissolved in organic carbonates: propylene carbonate (PC), dimethyl or diethyl carbonate (DMC or DEC), ethyl methyl carbonate (EMC), and mixtures of DMC or DEC with ethylene carbonate (EC). The EC component provides a passivating SEI layer on a carbon anode where the E_{FA} of the anode lies above the LUMO of the carbonates, which is about 1.1 eV below the E_{FA} of Lithium. The carbonates are reasonably good solvents for Li salts and they have a relatively low viscosity, which results in a low activation energy for Li^+ -ion diffusion to give a $\sigma_{\text{Li}} > 10^{-3}$ S/cm at 20°C and a ready penetration into a porous electrode. The HOMO is about 4.3 eV below the E_{FA} of Lithium, which gives an electrolyte

Battery Components, Active Materials for. Figure 8

NASICON (NA Superlionic CONductor) framework structure, which is the same as that of hexagonal $\text{Fe}_2(\text{SO}_4)_3$

window $E_g \approx 3.7$ eV. A carbonate electrolyte decomposes at a voltage $V > 4.9$ V versus Lithium; an SEI layer can stabilize the Ni, Mn oxides with cathode voltages in the interval $4.3 < V < 4.9$ V, but at the expense of a larger activation energy for Li^+ -ion transfer across it. However, this ΔH_m can be reduced either by doping to remove Ni from the surface or by coating the particles with a thin layer of a mixed Li^+ -ion/electronic conductor that replaces the SEI layer and is not removed by the volume changes that accompany charge/discharge cycling. With this strategy, an effective electrolyte window $E_g^{\text{eff}} \approx 3.8$ eV can be created. However, organic electrolytes are flammable, which raises safety concerns where an SEI layer is formed on the anode. Ionic liquids are not flammable and have a larger window, but they are too viscous to be practical unless they are blended with a less viscous liquid. Carbonate-ionic liquid blends that are not flammable have been demonstrated, but they are more viscous than a pure liquid carbonate and the carbonate component determines the operative electrolyte window. The loss of rate capability must be weighed against the nonflammable property in any blend of a carbonate with an ionic liquid.

Alternatively, the salt LiAlCl_4 dissolved in the inorganic liquid SO_2 has been proposed [7]; this Li^+ -ion electrolyte has a good room temperature $\sigma_{\text{Li}} = 7 \times 10^{-2}$ S/cm and is nonflammable; its electrolyte window may be too small to be competitive with the carbonates, but it deserves to be explored for Li batteries of lower voltage.

Insertion Compounds for Li-Ion Secondary Batteries

Anodes with Li^+ -Ion Liquid Electrolytes

In a liquid-carbonate electrolyte, dendrites form on an elemental Lithium anode that can grow across the electrolyte to short-circuit a cell on repeated cycling. Therefore, carbon or an alloy buffered by carbon is used with a liquid electrolyte [8].

Graphite has the layered structure of Fig. 9a and Li can be inserted rapidly and reversibly between the layered sheets to create sites capped by six C atoms and form LiC_6 , Fig. 9b, c. Similar reactions with graphitic sheets occur for the several different forms of carbon; but with a 2D insertion that shifts neighboring

graphene sheets relative to one another, a more amorphous type of carbon is preferred over large crystallites of graphite. A carbon anode into which Li^+ ions from the cathode are inserted on an initial charge, Eq. 12, is commonly used in Li^+ -ion rechargeable batteries. However, the E_{FA} of the reduced carbon in LiC_6 lies above the LUMO of a carbonate electrolyte, so on the initial charge it consumes irreversibly Li^+ ions from the cathode in the formation of a non-blocking SEI layer on the carbon unless the SEI layer is formed on the anode before battery assembly. Moreover, if a fast charge raises the charging voltage above Li^+/Li^0 , Lithium is plated out on the SEI layer, which introduces the possibility of dendrite formation with a catastrophic short circuit within the cell after repeated cycling. This problem limits the rate of charge unless the E_{FA} is at least 0.5 eV below Li^+/Li^0 . With a carbon anode at ca. 0.2 V vs Li^+/Li^0 , this problem introduces complexity in the safety management of a Li^+ -ion battery with a flammable electrolyte. To eliminate irreversible capacity loss due to SEI formation on the initial charge and to increase the rate of charge while simplifying safe battery management, it is necessary to introduce an insertion-compound anode giving a voltage versus Lithium greater than 1.0 V, but preferably less than 1.5 V. The spinel $\text{Li}_4\text{Ti}_5\text{O}_{12}$ gives a constant voltage versus Lithium of $V = 1.5$ V, but its capacity is disappointing. Preliminary studies have shown a layered niobate having a single-phase solid-solution Li insertion between 1.2 and 1.6 V versus Lithium has a higher capacity than that of $\text{Li}_4\text{Ti}_5\text{O}_{12}$, a good rate capability, and a promising cycle life; but Nb is more expensive than Ti and a fully satisfactory, safe anode material has yet to be accepted. The secondary Li^+ -ion batteries using a liquid electrolyte are therefore identified by their insertion-compound cathode. The Li^+ ion is small enough to be inserted into the interstices of a close-packed anion array.

Cathodes with Li-Ion Liquid Electrolytes

Layered Sulfides [9]. The MS_2 ($M = \text{Ti}, \text{V}, \text{V}_{0.5}\text{Cr}_{0.5}$) sulfides have the layered structure of Fig. 10 in which strongly bonded sheets of edge-shared $\text{MS}_{6/3}$ octahedra are held together by weak Van der Waals bonds. In the late 1960s, it was reported that Li can be intercalated (inserted) reversibly between the TiS_2 layers to give the

Battery Components, Active Materials for. Figure 9
Structure of (a) graphite, (b) graphene stacking in LiC_6 , and (c) LiC_6

solid-solution reaction Li_xTiS_2 ($0 \leq x \leq 1$) with the voltage profile of Fig. 11 for a Li/LiClO_4 in PC/TiS_2 cell. However, catastrophic failures due to dendrite formation on the Lithium anode forced consideration of an anode that would lower the cell voltage to where the cell would not be competitive with secondary cells having an aqueous electrolyte. Nevertheless, this early report raised awareness that the designer of a cathode material for a Li^+ -ion rechargeable battery should look to insertion compounds capable of providing a larger voltage versus Lithium than 2.5 V. However, the designer must not only identify a host structure into/

from which Li can be inserted/extracted reversibly, but also consider the limiting E_{FC} of the host structure and whether its E_{FC} can be matched to the HOMO of the electrolyte. For this latter consideration, it is instructive to consider the limiting E_{FC} of a layered sulfide.

Figure 12a illustrates schematically the energy density of one-electron states of TiS_2 versus their energy ϵ relative to the E_{FA} of a Lithium anode. The outer s and p electrons of the Ti and S atoms are primarily involved in the strong Ti–S bonding. The ionic and covalent components of this bonding create a filled broad band of one-electron states that have a primarily S-3 p

Battery Components, Active Materials for. Figure 10
Layered TiS_2 and LiTiS_2 structures

Battery Components, Active Materials for. Figure 11
 $V(x)$ versus Lithium profile for Li_xTiS_2 and $\text{Li}_{2x}[\text{Ti}_2]\text{S}_4$,
 $0 \leq x \leq 1$

character separated by an energy gap from an empty broad band of states that have a primarily Ti-4s character. These bands have similar energies in all the MS_2 layered compounds, but the bottom of the M-4s band falls progressively with increasing atomic number of the M atom. Empty Ti-3d states lie in the energy gap between these two bands. The cubic component of the site symmetry of a Ti(IV) cation splits the σ -bonding and π -bonding 3d orbitals by an energy Δ_c ; the σ -bonding states, not shown, lie above the bottom of the Ti-4s band and the π -bonding states lie in the energy gap between the broad Ti-4s and S-3p bands.

The trigonal component of the site symmetry splits the π -bonding 3d states into a lower, orbitally nondegenerate a_1 band and a higher, orbitally two-fold-degenerate e_π band. The Fermi energy of stoichiometric TiS_2 lies in a small energy gap between the bottom of the Ti- a_1 band and the top of the S-3p bands. Intercalation of Li^+ ions is neutralized by electrons entering the Ti- a_1 band; as E_{FC} rises with x in Li_xTiS_2 , the voltage versus Lithium drops smoothly in this single-phase solid-solution reaction, Fig. 11. The $\text{Ti}^{4+}/\text{Ti}^{3+}$ couple of Fig. 12a actually lies in an itinerant-electron a_1 band that is half-filled in LiTiS_2 ; however, displacement of Li to the tetrahedral sites of the Li layer in $\text{Li}_{1+x}\text{TiS}_2$ raises the $\text{Ti}^{3+}/\text{Ti}^{2+}$ couple to just below the Ti-4s band.

As the atomic nuclear charge increases from Ti to V to Cr, the 3d electrons become more tightly bound to the nucleus, which lowers their energies. The E_{FC} of VS_2 is pinned at the top of the S-3p bands, Fig. 12b. Pinning of E_{FC} occurs because, as the cation- d -like states move from above to below the top of the bonding anion- p bands, the empty antibonding states remain above the anion- p bonding states; but the empty antibonding states change their character from primarily cation- d to primarily anion- p while retaining their d -orbital symmetry. On the other hand, if the cation- d states fall too far below the top of the anion- p bands, the holes in the antibonding states become trapped in purely anion- p antibonding states of a S-S bond to create the $(\text{S}_2)^{2-}$ ion. The Cr(IV) formal valence state cannot be accessed because a localized-electron Cr(IV)/Cr(III) redox couple lies too far below the top of the

Battery Components, Active Materials for. Figure 12

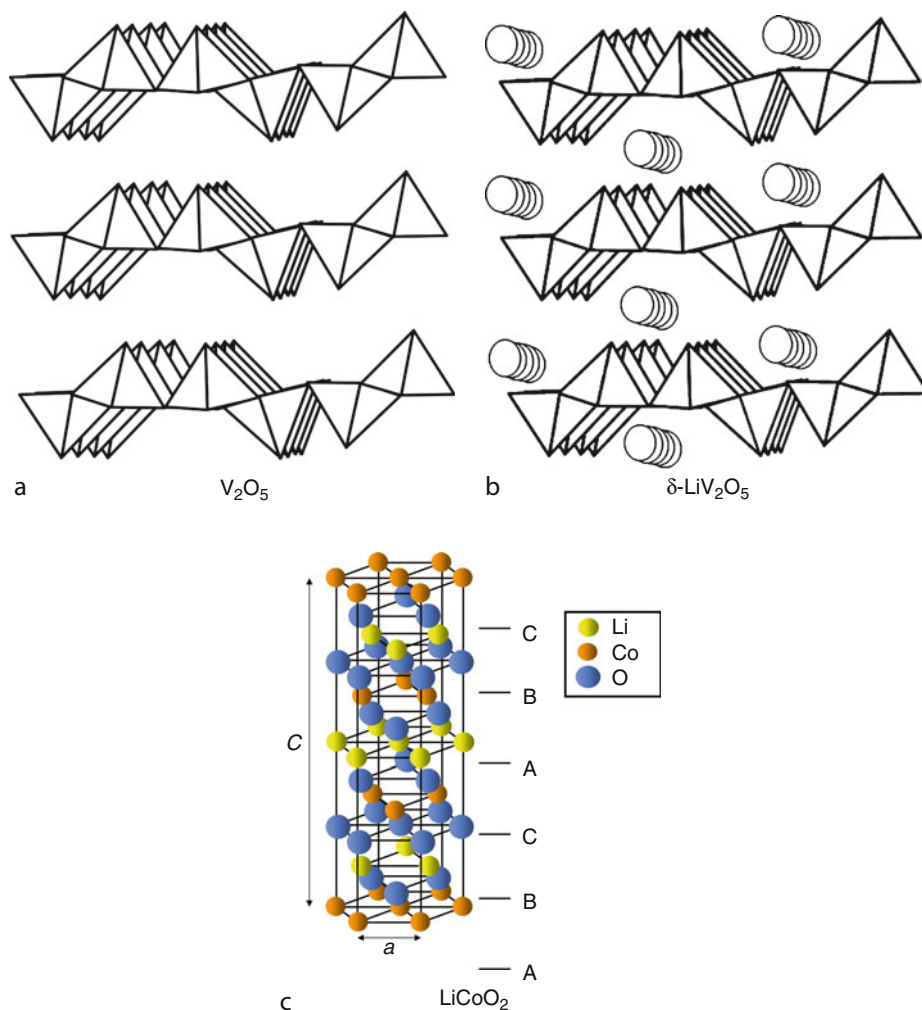

Energies of the bottom of the 4s band, the top of the S-3p bands, and π -bonding d-electron energies relative to the E_{FA} of Lithium for TiS_2 , VS_2 , and LiCrS_2 . In $\text{Li}_{1+x}\text{MS}_2$, all the Li occupy tetrahedral sites of the Li layer and the M(III)/M(II) levels are raised to give $V = 0.5$ V and 1.0 V, respectively, for $\text{Li}_{1+x}\text{TiS}_2$ and $\text{Li}_{1+x}\text{VS}_2$; the Cr(III)/Cr(II) level is raised above the bottom of the 4s band so that Li insertion into CrS_2 displaces Cr^0

S-3p bands. However, $\text{V}_{0.5}\text{Cr}_{0.5}\text{S}_2$ can be stabilized in the layered MS_2 structure, and reduction of this host by the intercalation of Li into $\text{Li}_x\text{V}_{0.5}\text{Cr}_{0.5}\text{S}_2$ accesses the V(V) to V(III) formal valences [10]. A flat $V \approx 2.7$ V for $x < 0.5$ in $\text{Li}_x\text{V}_{0.25}\text{Cr}_{0.75}\text{S}_2$ signals that the top of the S-3p bands is about 2.7 eV below the E_{FA} of Lithium. This limitation on the voltage in these sulfides motivated study of the extraction of Li from similarly layered oxides since the top of the O-2p bands would be below the top of the S-3p bands.

Layered Oxides. Most solid cathode hosts are transition-metal oxides in which E_{FC} lies in either a mixed-valent redox couple or a narrow band of d-electron states. The PbO_2 cathode of the lead–acid battery is an exception; its E_{FC} is located in a narrow Pb-6s band well-separated from the broad, empty Pb-6p band because Pb is heavy.

A layered transition-metal MO_2 oxide analogous to TiS_2 does not exist; the electrostatic repulsive forces between the oxygen layers are stronger than any Van der Waals bonding, which is much weaker in an oxide than in the chalcogenides. However, where the transition-metal M atom has no d electrons, or at most one d

electron, and is too small to be stable in an octahedral site, it may undergo a ferroic M-atom displacement to form a short $\text{M} = \text{O}$ bond with one oxygen of the octahedral site and a long $\text{O} \cdots \text{M}$ bond on the opposite side. These displacements create site dipoles that can stabilize a layered oxide as is illustrated by the structure of V_2O_5 , Fig. 13a. On the other hand, several LiMO_2 oxides form rock-salt structures in which the Li^+ and M(III) ions occupy alternate layers of M(III) octahedral sites, Fig. 13c. The sheets of edge-shared $\text{MO}_{6/3}$ octahedra are analogous to those of TiS_2 , but the stacking between sheets gives hexagonal-close-packed sulfide ions in TiS_2 , cubic-close-packed oxide ions in LiMO_2 . The layers can also be stacked to give trigonal-prismatic sites between the layers. Moreover, Li can be either extracted, $\text{Li}_{1-x}\text{MO}_2$, or inserted, $\text{Li}_{1+x}\text{MO}_2$. Insertion of more than one Li per formula unit displaces Li^+ ions from octahedral to tetrahedral sites in the Li layer to form Li_2MO_2 in a two-phase reaction. The two-phase insertion reaction LiVS_2 – Li_2VS_2 gives a voltage of 1.0 V versus Lithium, and an SEI layer is formed on the electrode. The $\text{Li}_{1-x}\text{MO}_2$ oxides are of interest as cathodes.

Battery Components, Active Materials for. Figure 13
The structures of (a) V_2O_5 , (b) $\delta\text{-LiV}_2O_5$, and (c) $LiMO_2$

Extraction of Li from $LiMO_2$ oxides creates $M(IV)/M(III)$ mixed valence on the M atoms. Where the M atoms have a localized spin S associated with a cation configuration $3d^n$, the mobile electron of the mixed-valent system moves diffusively in a hopping transfer $d^{n+1} + d^n = d^n + d^{n+1}$ between like atoms on equivalent lattice sites. In this case, the d^n/d^{n+1} configuration of an $M(IV)/M(III)$ mixed-valent system may be considered a redox couple because the time for a hop is long compared to the period of a lattice vibration that traps the mobile electron or hole at a single site. Where the empty d -electron states lie close to the top of an anion- p band, the electrons may occupy a narrow

band of itinerant-electron states as in TiS_2 and VS_2 . Electrons in a partially filled band of itinerant-electron states give a metallic conductivity, those in redox couples require an activation energy for a hop to a like neighbor.

The energies of successive redox couples, for example, $M(IV)/M(III)$ to $M(III)/M(II)$, are separated by an on-site electron–electron electrostatic repulsive energy. In the case of $Cr(III)$ in Fig. 12c, the cubic crystal-field splitting is added to this electrostatic on-site energy to raise the $Cr(III)/Cr(II)$ energy to above the bottom of the Cr -4s band while the $Cr(IV)/Cr(III)$ couple lies below the top of the S -3p bands. Insertion of Li into

LiCrS_2 results in $\text{Li}_2\text{S} + \text{Cr}^0$; extraction of Li results in $(\text{S}_2)^{2-}$ formation. On the other hand, the electrons in the narrow $V-a_1$ band with E_{FC} pinned at the top of the $S-3p$ bands allows access to both the $V(V)/V(IV)$ and $V(IV)/V(III)$ mixed-valence states without any energy gap between them [10].

The Co(III) ions in LiCoO_2 are in their low-spin $S = 0$ state, but the initial Co(IV) ions appearing on removal of Li in $\text{Li}_{1-x}\text{CoO}_2$ are in their high-spin $S = 5/2$ state [11]; the holes are trapped at a single Co(IV) site. However, in the range $0.05 \leq x \leq 0.45$, the voltage is flat at $V \cong 4.0$ V versus Lithium, which signals a two-phase reaction between a Li-rich phase containing high-spin Co(IV) and a Li-poor phase containing low-spin Co(IV/III) ions with holes in an itinerant-electron π^* band [12]. For $x \geq 0.55$, a new phase with different stacking of the CoO_2 sheets begins to appear as oxygen is evolved and/or H^+ ions from the organic electrolyte are inserted so as to retain the $\text{Co(IV)}/\text{Co}$ ratio at about 0.45 [13]. The outgassing of oxygen shows that the holes in the π^* band have sufficient $\text{O-}2p$ character, at least at a grain surface, to become trapped in peroxide ions $(\text{O}_2)^{2-}$ followed by $2(\text{O}_2)^{2-} = 2\text{O}^{2-} + \text{O}_2\uparrow$. Clearly, the $\text{Li}_{1-x}\text{CoO}_2$ electrode reaches its *intrinsic limit* at a ratio $\text{Co(IV)}/\text{Co} \approx 0.45$; this limit is above the HOMO of the electrolyte, so the electrolyte is not being decomposed aside from loss of inserted H^+ ions. The intrinsic limit restricts the practical capacity of $\text{Li}_{1-x}\text{CoO}_2$ to only 50% of the theoretical capacity, that is, to a $Q = 140$ mAh/g.

A cell with a carbon anode forms an LiC_6 phase during an initial charge from the discharged cathode LiCoO_2 , and formation of an SEI layer on the reduced carbon during the initial charge reduces further the available capacity of the cell unless the SEI layer on the anode is formed before the cell assembly. Moreover, by fabricating the cell with a discharged cathode, it is the capacity of the cathode that determines the capacity of the cell. Nevertheless, the E_{FA} of the carbon anode is only 0.2 eV below the E_{FA} of Lithium, so the cell has a high specific energy QV because of its $V \approx 3.8$ V. The cell also has a high volumetric energy density, which is why it captured the market for laptop computers, cell telephones, and other handheld devices. The *tap density* of an electrode refers to the density of active particles that can be packed into a given volume, and a high tap

density of LiCoO_2 is responsible for the high volumetric energy density.

Cobalt is expensive and toxic, so it was natural to try substitution of Ni for Co. However, it proves difficult to prepare well-ordered LiNiO_2 . The maximum Ni substitution for Co in a layered phase with well-ordered Li^+ ions is $\text{LiCo}_{0.15}\text{Ni}_{0.85}\text{O}_2$ [14]. Since the holes in $\text{Li}_{0.5}\text{CoO}_2$ occupy a π^* band whereas those on low-spin Ni(III) occupy a σ^* band of higher energy, the $\text{LiCo}_{0.15}\text{Ni}_{0.85}\text{O}_2$ system gives a loss of O_2 and/or H^+ insertion only for $(1-x) < 0.35$, which gives a $Q = 200$ mAh/g. Addition of a small amount of Al in $\text{LiAl}_{0.05}\text{Co}_{0.15}\text{Ni}_{0.8}\text{O}_2$ improves the ordering of the Li and optimizes the cyclability of this cathode.

The transfer of M atoms into vacant sites of the Li layer on Li extraction requires their transfer via a tetrahedral site of the interstitial space. The low-spin Co(IV/III) and Ni(IV/III) cations have a strong octahedral-site preference, so transfer to the vacancies in the Li layer is kinetically inhibited below 300°C . However, ions like Fe(III) , Mn(II) , and Cr(VI) have a strong tetrahedral-site preference and are easily displaced to the interstitial tetrahedral sites on Li removal. Therefore, LiFeO_2 does not retain its structure on Li extraction. The disproportionation reactions $2\text{Mn(III)} = \text{Mn(II)} + \text{Mn(IV)}$ and $3\text{Cr(IV)} = 2\text{Cr(III)} + \text{Cr(VI)}$ introduce Mn(II) and Cr(VI) ions into the interstitial space to block insertion of Li back into the structure. Therefore, in order to eliminate Co and to take advantage of the pinning of the $\text{Ni(IV)}-\text{Ni(II)}$ valence states at the top of the $\text{O-}2p$ bands, the $\text{LiNi}_{0.5}^{(\text{II})}\text{Mn}_{0.5}^{(\text{IV})}\text{O}_2$ structure was investigated [15]; the Mn(IV) ion has a strong octahedral-site preference and the $\text{Mn(V)}/\text{Mn(IV)}$ redox couple lies well below the top of the $\text{O-}2p$ bands where the disproportionation reaction $3\text{Mn(IV)} = 2\text{Mn(III)} + \text{Mn(VI)}$ is inhibited. However, the mean size of the Ni(II) and Mn(IV) ions is too large for good ordering of the Li^+ ions in $\text{Li}(\text{Ni}_{0.5}\text{Mn}_{0.5})\text{O}_2$ to be easily obtained. Therefore, considerable attention has been given to $\text{Li}(\text{Ni}_{0.5-x}\text{Co}_{2x}\text{Mn}_{0.5-x})\text{O}_2$ with $x \leq 1/6$ where the $\text{Ni(III)}/\text{Ni(II)}$ and $\text{Ni(IV)}/\text{Ni(III)}$ mixed valences are accessed without a step in the voltage profiles on passing from one to the other because of E_{FC} pinning. Moreover, solid solutions of these LiMO_2 oxides with $\text{Li}(\text{Li}_{1/3}\text{Mn}_{2/3})\text{O}_2$, commonly designated Li_2MnO_3 , as a randomly intercalated second phase exhibit, after an

initial charge, a high reversible capacity of 250 mAh/g even though Li_2MnO_3 itself is not electrochemically active [16]. The voltage profiles of these solid solutions exhibit two distinct regions during the first charge, an initial sloping range corresponding to the oxidation of the Ni(II) to Ni(IV) and the Co(III) to Co(IV) followed by a plateau at $V \approx 5.5$ V. The plateau at 4.5 V appears to signal oxidation of the electrolyte. The excess Li_2MnO_3 increases the Mn(IV) concentration, which lowers further the top of the O-2- bands and thus increases the intrinsic voltage limit of the layered oxide. The passivating SEI layer formed from the electrolyte at voltages $V > 4.3$ V inhibits Li^+ -ion transfer across the electrode/electrolyte interface, but coating with an oxide layer that transports Li^+ ions suppresses formation of the electrolyte SEI layer to allow fast cycling. Nevertheless, these layered oxides must compete against spinel cathodes containing Ni(II) and Mn(IV).

Vanadium Oxides. Several intermediate phases appear between V_2O_3 and V_2O_5 ; Li insertions into V_2O_5 and V_6O_{13} were investigated in the 1970s, and an amorphous or low-crystallinity VO_x with a polyethylene oxide (PEO) electrolyte is used in a Li/PEO/ VO_x secondary battery for stationary storage of electrical energy [17].

Figure 13a shows the structure of orthorhombic V_2O_5 ; corner-shared paired chains of distorted VO_6 octahedra parallel to the c -axis share edges to create

c -axis zigzag chains. Ferroic c -axis displacements of V atoms in the paired chains create asymmetric c -axis bonds $0 \dots V = O$, which places the V atoms in square-pyramidal sites. These chains share corners in the $a-b$ planes with antiferroelectric coupling across shared edges to create the $a-b$ layers of Fig. 13a. Li^+ ions can be inserted reversibly into the b -axis tunnels to form $\delta\text{-LiV}_2\text{O}_5$ via an intermediate $\varepsilon\text{-Li}_x\text{V}_2\text{O}_5$ phase.

In the range $0 \leq x \leq 1$ of $\text{Li}_x\text{V}_2\text{O}_5$, reduction of the vanadium on Li^+ -ion insertion only tilts the square-pyramidal sites of the $a-b$ planes, but three phases can be distinguished: α ($0 \leq x \leq 0.1$), ε ($0.35 \leq x \leq 0.7$), and δ ($0.9 \leq x \leq 1.0$). The reversible insertion of Li into V_2O_5 gives a voltage profile versus Lithium with two plateaus, one at 3.4 V for the $\alpha + \varepsilon$ range $0.1 \leq x \leq 0.35$ and the other at 3.2 V for the $\varepsilon + \delta$ range $0.7 \leq x \leq 0.9$. On further Li insertion, the voltage drops abruptly to 2.4 V followed by a monotonic decrease with x to about 1.5 V over the range $1 < x < 3$. Cycling through the first-order transition at $x = 1$ damages the crystallites and lowers the cyclability. However, insertion into amorphous or low-crystallinity V_2O_5 allows faster and better cyclability. Insertion of 1.5 Li per V atom gives a relatively large capacity.

The structure of V_6O_{13} shows how the particles of low-crystallinity or amorphous VO_x can accommodate Li^+ -ion insertion into 1D tunnels. Figure 14 shows the structures of V_2O_5 and V_6O_{13} projected, respectively, onto its (001) and (010) plane, which illustrates how

Battery Components, Active Materials for. Figure 14

Comparison of structures of V_2O_5 projected onto its (001) plane and V_6O_{13} onto its (010) plane

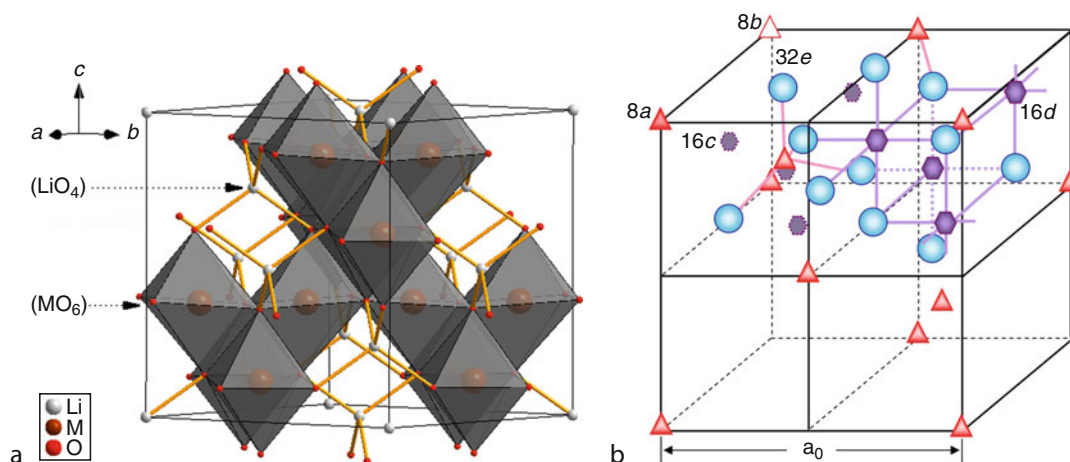

the V_6O_{13} structure can be derived from that of V_2O_5 . Removal of oxygen from every third a – c oxygen plane of V_2O_5 is followed by a shear, which leaves tunnels for Li^+ -ion insertion as in V_2O_5 . The shear planes need not be ordered as in V_6O_{13} .

These observations have led to the synthesis of a two-dimensional (2D) pseudocrystalline phase containing segments of three planes similar to those of V_2O_5 that are displaced from one another by a slip plane. This structure provides an insertion of up to two Li atoms per formula unit with a monotonic voltage decrease with x , except for a small step at $x = 1.5$, over the voltage range $2.5 < V < 3.4$ V versus Lithium. Nevertheless, there is a gradual capacity fade with cycle number.

The voltage profile of $Li_xV_6O_{13}$ shows small steps at $x = 1, 2$, and 3 as the voltage decreases from 2.8 to 2.4 V versus Lithium and a drop from 2.4 to 2.1 V in the interval $3 < x < 4$ that is followed by a gradual drop to 2.0 V as x approaches 6 . The steps appear to correspond to Li^+ -ion ordering with electrons entering $V - 3d$ bands rather than localized redox couples; the electronic states change character from $V - 3d$ with a large $O - 2p$ component to a dominant $V - 3d$ character with increasing x . Capacity fading on cycling makes this material not competitive as a cathode for a secondary battery.

Spinel. The $A[M_2]O_4$ spinels have a cubic-close-packed array of oxygen atoms with M-site cations in half of the octahedra, the $16d$ sites of space group $Fd\bar{3}m$ of Fig. 15. The $[M_2]O_4$ array represents a strongly bonded framework with A atoms in the interstitial tetrahedral sites $8a$. The empty $16c$ octahedral sites share faces with the $8a$ sites to form, with the $8a$ sites, a 3D-interconnected interstitial space. On Li^+ -ion insertion into an empty $16c$ site, the coulombic repulsive force between the Li^+ -ion and the near-neighbor A-site cations pushes all the A-site cations in a cascade into the $16c$ sites [18].

In the case of magnetite, $Fe[Fe_2]O_4$, insertion of one Li per formula unit produces an ordered rock-salt array with Fe remaining on all the $16d$ sites and Li and Fe randomly distributed over the $16c$ sites. Further insertion of Li extrudes Fe reversibly from the $16c$ sites to form the ordered rock-salt structure $Li_2[Fe_2]O_4$ and amorphous Fe^0 . From this observation, it was clear that Li insertion into the system $Li_{1+y}[Mn_2]O_4$ ($0 < y \leq 1$) would place Li^+ ions in the octahedral $16c$ sites and Li extraction in the system $Li_{1-y}[Mn_2]O_4$ ($0 < y \leq 1$) would leave the Li^+ ions in tetrahedral $8a$ sites. Moreover, with only Li^+ ions in the 3D interstitial space, a fast Li^+ -ion transport could be anticipated. The voltage profile of Fig. 16 for the system $Li_x[Mn_2]O_4$, $0 \leq x \leq 2$, shows a 1-V step at $x = 1$ where the Li^+ ions

The $V(x)$ versus Lithium profile for $\text{Li}_x[\text{Mn}_2]\text{O}_4$ showing a 1 eV step in the M(IV)/M(III) redox couple at $x = 1$

shift from tetrahedral to octahedral sites. This remarkable 1-eV shift in the energy of the Mn(IV)/Mn(III) couple shows that the energy of an active redox couple is sensitive to the Madelung ionic electrostatic energy of the oxide.

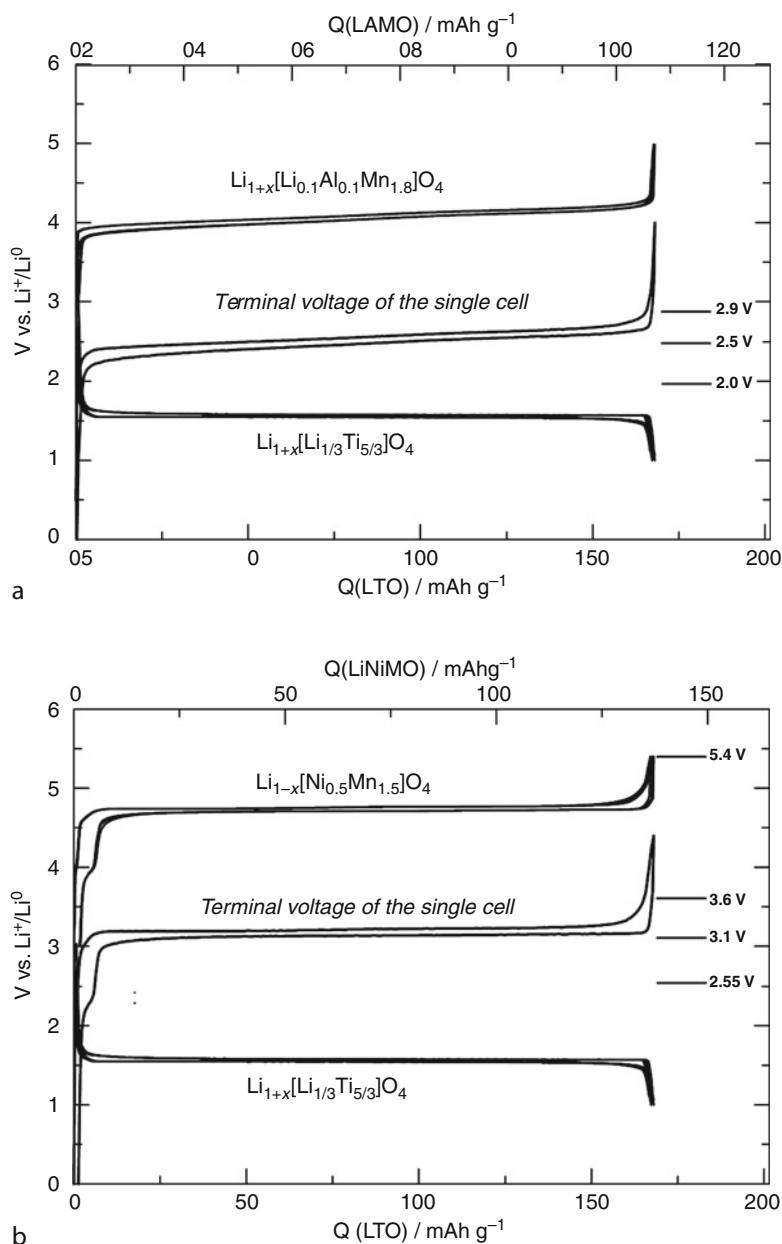

In contrast, the voltage profile of Li insertion into the thiospinel framework $[\text{Ti}_2]\text{S}_4$ shows no step at $x = 1$ [19]; the profile of $\text{Li}_x[\text{Ti}_2]\text{S}_4$, $0 \leq x \leq 2$, is nearly identical to that for the layered system Li_xTiS_2 , which shows that the Li^+ ions occupy only octahedral 16c sites for all x in $\text{Li}_x[\text{Ti}_2]\text{S}_4$. Preparation of the thiospinel $\text{Li}[\text{Ti}_2]\text{S}_4$ is not straightforward; the thiospinel framework $[\text{Ti}_2]\text{S}_4$ is prepared by chemical extraction of tetrahedral-site Cu^+ from the thiospinel $\text{Cu}[\text{Ti}_2]\text{S}_4$. In both the layered TiS_2 and the spinel framework $[\text{Ti}_2]\text{S}_4$, the octahedral $\text{TiS}_{6/3}$ sites share only edges, not corners, with neighboring $\text{TiS}_{6/3}$ sites; only the shape of the interstitial space has been changed from 2D to 3D. The 2D interstitial space of LiTiS_2 allows intercalation of other species than the Li^+ ions whereas the 3D interstitial space of the strongly bonded spinel framework does not.

The 1-V step in the voltage profile of $\text{Li}_x[\text{Mn}_2]\text{O}_4$ limits the capacity of this spinel to one Li^+ per two Mn atoms at either 3.0 V or 4.0 V versus Lithium. The flat 3.0 V plateau reflects a cubic to tetragonal transition of the $[\text{Mn}_2]\text{O}_4$ framework due to a cooperative Jahn–Teller site distortion where more than half of the 16d sites are occupied by Mn(III) ions. Octahedral-site,

high-spin Mn(III) ions have a localized spin $S = 2$ with one electron occupying an orbitally twofold-degenerate pair of σ -bonding e_σ orbitals; a site distortion to tetragonal symmetry removes the degeneracy, stabilizing an occupied ($3z^2 - r^2$) orbital at the expense of an empty ($x^2 - y^2$) orbital of the e_σ pair. A cooperative site distortion minimizes the elastic energy per site that it costs to distort a site from cubic symmetry.

The 8a sites consist of two interpenetrating face-centered-cubic arrays to form the diamond lattice. The small step in the 4.0-V plateau of Fig. 16 reflects an ordered $\text{Li}_{0.5}[\text{Mn}_2]\text{O}_4$ phase in which the Li^+ ions occupy only one of the two interpenetrating face-centered-cubic 8a arrays; two-phase separations occur either side of $x = 0.5$. The two-phase separation due to Li^+ -ion order enhances a surface disproportionation reaction $2\text{Mn(III)} = \text{Mn(II)} + \text{Mn(IV)}$ that is followed by Mn(II) dissolution into the electrolyte. The Mn(II) crosses over to the anode to poison Li^+ -ion mobility across the anode SEI layer. As a result, operation on the 4.0-V plateau is plagued by a reduction in capacity that increases with cycling. The Mn(II) dissolution represents a chemical reaction of the electrode with the electrolyte that is to be distinguished from oxidation of the electrolyte by an E_{FC} below the electrolyte HOMO. The progressive increase with cycling in the irreversible loss of capacity is referred to as a capacity fade; it limits the cycle life of the cell. Substitution of Ni or Al and some Li for Mn suppresses any Jahn–Teller framework distortion near $x = 1$; it also disorders the Li^+ ions at $x = 0.5$ to reduce further the Mn(III)-ion concentration at the surface and hence the Mn(II) dissolution, but at the expense of the capacity of the cathode. Figure 17a shows charge/discharge curves for a $\text{Li}_{1-x}[\text{Al}_{0.1}\text{Li}_{0.1}\text{Mn}_{1.8}]\text{O}_4/\text{Li}_{1+x}[\text{Li}_{1/3}\text{Ti}_{5/3}]\text{O}_4$ cell that can undergo safely a fast recharge. At 55°C, this cell retains 80% of its rechargeable capacity after 3,600 cycles. Batteries of five cells connected in series deliver a nominal 12 V.

In the layered $\text{Li}_{1-x}\text{Co}_{0.15}\text{Ni}_{0.85}\text{O}_2$ system, pinning of E_{FC} at the top of the O-2p bands gave an intrinsic limit of 3.8 V versus Lithium for the Ni(IV)/Ni(III) couple. Removal of nearly all the Li from the layered oxide $\text{LiNi}_{0.5}\text{Mn}_{0.5}\text{O}_2$ containing Mn(IV) ions shows not only that Mn(IV) increases the voltage limit of the Ni(IV)/Ni(III) couple by lowering the top of the O-2p bands, but also that where E_{FC} is pinned, oxidation of

Battery Components, Active Materials for. Figure 17

Charge/discharge $V(x)$ versus Li^+/Li^0 for (a) $\text{Li}_{1-x}[\text{Al}_{0.1}\text{Li}_{0.1}\text{Mn}_{1.8}]\text{O}_4$ and (b) $\text{Li}_{1-x}[\text{Ni}_{0.5}\text{Mn}_{1.5}]\text{O}_4$ with $\text{Li}_{1+x}[\text{Li}_{1/3}\text{Ti}_{5/3}]\text{O}_4$ to give terminal single-cell voltages (By courtesy of Prof. T. Ohzuku)

Ni(II) to Ni(IV) occurs without a step in the voltage profile. Moreover, pinning of E_{FC} gives the flat voltage profile of Fig. 17b; at room temperature, Li is removed over the range $0 < x < 1$ at $V \approx 4.7$ V, which is just below the carbonate-electrolyte decomposition voltage above 4.9 V versus Lithium. Batteries with only four

$\text{Li}_{1-x}[\text{Ni}_{0.5}\text{Mn}_{1.5}]\text{O}_4/\text{Li}_{1+x}[\text{Li}_{1/3}\text{Ti}_{5/3}]\text{O}_4$ cells connected in series can deliver a nominal 12 V. Lowering the top of the O-2p bands in the spinel structure increases the intrinsic voltage limit of the oxide. In contrast, the Ti(IV) ion of $\text{Li}_{1-x}[\text{Ni}_{0.5}\text{Mn}_{1.5}]\text{O}_4$ prevents access to even the Ni(III) oxidation state. Unfortunately, although

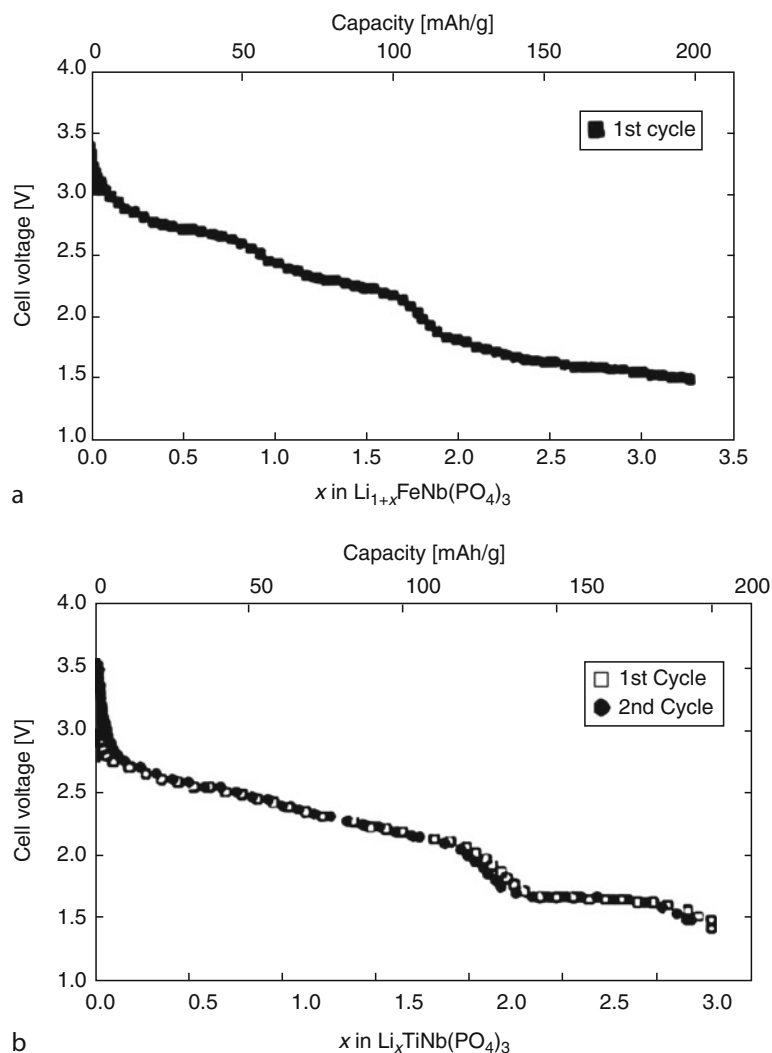

the SEI layer on $\text{Li}[\text{Ni}_{0.5}\text{Mn}_{1.5}]\text{O}_4$ appears to stabilize the cathode at room temperature, raising the temperature to 60°C can introduce a capacity fade on cycling. Coating of the surface of the active oxide particles with another oxide permeable to Li^+ ions has been shown to reduce the activation energy for Li^+ -ion transfer across the SEI layer as well as the capacity fade at 60°C . The spinel $\text{Li}_{0.5-x}[\text{Ni}_{0.5-x}\text{Cr}_{2x}\text{Mn}_{1.5-x}]\text{O}_4$ ($x \cong 0.05$) appears to stabilize the cathode at 60°C without sacrifice of the capacity since the $\text{Cr(IV)}/\text{Cr(III)}$ couple is accessible and small Cr concentration inhibit the disproportionation of Cr(IV) into Cr(VI) and Cr(III) and are sufficient to remove Ni from the particle surface. The development of 12 V batteries based on spinel insertion compounds is targeted for plug-in hybrid vehicles and electrical-energy storage in solar-powered homes. The goal is a life in excess of 10 years and a driving range per charge in excess of 200 miles at an acceptable dollar and environmental cost.

NASICON Framework [20]. Use of a solid Na^+ -ion electrolyte in the Na-S battery stimulated a search in the early 1970s for an improved Na^+ -ion conductor. This search concentrated on open framework structures that were electronic insulators and hosts to mobile Na^+ ions. One of these framework structures was that of the system $\text{Na}_{1+3x}\text{Zr}_2(\text{P}_{1-x}\text{Si}_x\text{O}_4)_3$ with $0 \leq x \leq 1$ having the structure of hexagonal $\text{Fe}_2(\text{SO}_4)_3$ pictured in Fig. 8. This system with $x \approx 2/3$ was named NASICON to signify it is a NA SuperIONic CONductor, and the host framework is now referred to in the literature as the NASICON framework. Substitution of Na^+ ions by Li^+ ions and substitution of a smaller Ti(IV) for Zr(IV) gives LISICON having the same framework; up to 5 Li^+ ions per formula unit can be accommodated in this framework. Substitution of tetrahedral polyatom anions for oxygen opens up the interstitial space for fast Li^+ -ion motion, and substitution for Zr of a smaller transition-metal atom having a lower-energy redox couple makes this framework a candidate host for the cathode of a Li^+ -ion secondary battery. In this host, the octahedral-site cations share corners with the polyatom tetrahedral anions and *vice versa*, which isolates the transition-metal cations from one another. Therefore, the $3d$ configurations at the transition-metal ions are localized, so the successive redox couples are separated from one another by a finite energy gap. This gap may be large, as in the

separation of the $\text{Cr(IV)}/\text{Cr(III)}$ and $\text{Cr(III)}/\text{Cr(II)}$ couples pictured in Fig. 12b or it may be small as between $\text{V(V)}/\text{V(IV)}$ and $\text{V(IV)}/\text{V(III)}$ couples in $\text{Li}_{3-x}\text{V}_2(\text{PO}_4)_3$, vide infra. Since this framework can accommodate up to 5 Li atoms without influencing significantly the redox energies on the octahedral-site cations, the framework lends itself to an examination not only of the influence on the redox energies of the counter cation within the polyatom anion, but also the relative energies of different redox couples for a fixed tetrahedral anion [21].

The $\text{Fe(III)}/\text{Fe(II)}$ redox energy of $\text{Fe}_2(\text{SO}_4)_3$ is at 3.6 eV, those of isostructural $\text{Fe}_2(\text{MoO}_4)_3$ and $\text{Fe}_2(\text{WO}_4)_3$ are at 3.0 eV below the E_{FA} of Lithium. This finding demonstrates that the stronger the covalent bonding in the polyatom anion, the weaker is the bonding of the oxygen to the octahedral-site cation and therefore the more stable is the transition-metal redox energy. This electrochemical result provides a direct measure of the magnitude of this *inductive effect* [22]. It shows that a redox energy can be tuned not only by the position of the guest ion in the interstitial space of the spinel $\text{Li}_x[\text{Mn}_2]\text{O}_4$ or the redox energy of a near-neighbor cation coexisting in an equivalent lattice site as in $\text{Li}(\text{Ni}_{0.5}\text{Mn}_{0.5})\text{O}_2$ versus $\text{Li}(\text{Ni}_{0.8}\text{Co}_{0.2})\text{O}_2$, but also by the counter cation in a polyatom anion. Accordingly, the $\text{Fe(III)}/\text{Fe(II)}$ redox couple in $\text{Li}_{3+x}\text{Fe}_2(\text{PO}_4)_3$ is 2.8 eV below the E_{FA} of Lithium. The 0.8 eV shift of the $\text{Fe(III)}/\text{Fe(II)}$ redox couple on changing from $(\text{SO}_4)^{2-}$ to $(\text{PO}_4)^{3-}$ is the same for all the redox energies of the NASICON framework.

As an illustration of how the structure lends itself to locating the relative positions of the available redox energies, Fig. 18a shows the voltage profile for $\text{Li}_{1+x}\text{FeNb}(\text{PO}_4)_3$ showing discrete steps on passing from the $\text{Fe(III)}/\text{Fe(II)}$ to the $\text{Nb(V)}/\text{Nb(IV)}$ couple to the $\text{Nb(IV)}/\text{Nb(III)}$ couple at 2.8 eV, 2.3 eV, and 1.8 eV, respectively, below the E_{FA} of Lithium. The $\text{Ti(IV)}/\text{Ti(III)}$ couple at 2.5 eV in $\text{Li}_x\text{TiNb}(\text{PO}_4)_3$ overlaps the $\text{Nb(V)}/\text{Nb(IV)}$ couple at 2.5 eV to give the smooth voltage profile from 2.5 to 2.2 V shown in Fig. 18b. The relative energies of the redox couples with $(\text{SO}_4)^{2-}$ anions remain the same, but all are shifted by about 0.8 eV to lower energy. The voltage profile of a carbon-coated $\text{Li}_{3-x}\text{V}_2(\text{PO}_4)_3$ cathode versus Lithium shows a good cycle life over the interval $0 \leq x \leq 3$ with two-phase reactions at 3.59 V in the interval $0.5 \leq x \leq 1.0$

Battery Components, Active Materials for. Figure 18

Discharge $V(x)$ versus Li^+/Li^0 for (a) $\text{Li}_{1+x}\text{FeNb}(\text{PO}_4)_3$ and (b) $\text{Li}_x\text{TiNb}(\text{PO}_4)_3$

and 3.67 in the interval $1.0 \leq x \leq 2.0$ corresponding to the V(IV)/V(III) couple and 4.06 V over $2.0 \leq x \leq 3.0$ of the V(V)/V(IV) couple. The 0.08 eV step for the V(IV)/V(III) couple is due to ordering of the Li^+ ions into the unique interstitial site per formula unit between M-atom sites of the framework; the larger 0.4 eV step at $x = 2.0$ is the separation of the V(IV)/V(III) and V(V)/V(IV) couples. Carbon coating of the particles is needed to facilitate these two-phase reactions; the large separation of the transition-metal ions makes any electron transport diffusive, which limits the power capability with this framework unless small, carbon-coated particles are used.

Ordered Olivines LiMPO_4 . As in a spinel [23], in the olivine structure of Mg_2SiO_4 , the cations occupy half of the octahedral and one-eighth of the tetrahedral sites of a slightly distorted, close-packed anion array, but the olivine anion array is close-packed-hexagonal rather than close-packed-cubic. Moreover, two types of occupied octahedral sites are distinguishable, which leads to an ordering of Li^+ and M(II) ions in the LiMPO_4 olivines whereas they are disordered in the spinel $\text{V}[\text{LiM}]\text{O}_4$. The ordered MPO_4 array forms a 3D strongly bonded framework in which octahedral-site M atoms share corners within $a-c$ planes of an orthorhombic unit cell, Fig. 19; these $a-c$ planes are

Battery Components, Active Materials for. Figure 19
Structure of the ordered olivine LiFePO_4

bridged by the PO_4 tetrahedra and the guest Li^+ ions occupy 1D a -axis tunnels of edge-shared octahedra. Motion of the Li^+ ions to neighboring empty octahedral sites outside of the tunnels requires a larger activation energy than motion along the tunnels.

The M atoms of LiMPO_4 may be Mg, Mn, Fe, Co, Ni, or mixtures thereof. Of these possibilities, LiFePO_4 is the most promising cathode material; $\text{Li}_{1-x}\text{FePO}_4$ provides a flat $V = 3.45$ V versus Lithium. Removal of Li from LiMnPO_4 is difficult, but the Mn(III)/Mn(II) couple gives a more attractive $V = 4.1$ V. The Co(III)/Co(II) couple near 4.8 eV below the E_{FA} of Lithium is at the limit where a liquid-carbonate electrolyte becomes unstable.

It is not possible to substitute an aliovalent cation for Fe(II) in LiFePO_4 . Synthesis of LiFePO_4 from nonstoichiometric starting mixtures results in the dissolution of a separate phase to the surface of stoichiometric LiFePO_4 particles. Electrochemical removal of Li results in the formation of FePO_4 as a separate phase. This situation means that the electronic conductivity remains low and the voltage profile of $\text{Li}_{1-x}\text{FePO}_4$ is flat. In order for Li^+ ions to move in or out of a particle rapidly with the electron of an Fe(III)/Fe(II) couple, it

Battery Components, Active Materials for. Figure 20
Discharge $V(x)$ versus Li^+/Li^0 for C-coated Li_xFePO_4 with/without PPy for different rates for full discharge from C/10 = 10 h to 5 C = 12 min

is necessary to have an electronically conducting coat on a small nanosize particle that also not only makes electronic contact with the current collector, but also is permeable to Li^+ ions. This coat may be a phase rich in Li that is dissolved from the LiFePO_4 particle or carbon; the coat makes electronic contact with the current collector either by added inert carbon or by contact to an electronically conducting polymer that also contacts the current collector and has an active redox energy that overlaps the energy of the Fe(III)/Fe(II) couple of LiFePO_4 . Polypyrrole (PPy) and polyanniline (PANI) are two such polymers [24]. Figure 20 illustrates the voltage profile versus Lithium of carbon-coated LiFePO_4 with PPy for different charge/discharge rates. With a $V = 3.45$ V well below the 4.3 V limit imposed by the HOMO of the electrolyte, this cathode is safe; it also has an excellent cycle life. This cathode is used in secondary Li^+ -ion power batteries and is an attractive contender for the battery of a plug-in hybrid vehicle despite a redox energy that is 1 eV higher than would appear to be optimal for a carbonate electrolyte.

It should be noted that LiFePO_4 nanoparticles embedded in a carbon matrix make a composite that shows promise for the cathode of an electrochemical capacitor of higher energy density than a purely carbon cathode.

Secondary Batteries with Cathodes That Are Not Insertion Compounds

The cell of a *sodium–sulfur* battery, illustrated schematically in Fig. 21, consists of two liquid electrodes, molten sodium and sulfur, separated by a ceramic Na^+ -ion electrolyte; it operates in the 300–375°C range to maintain molten not only the sodium anode, but also both the sulfur cathode and the immiscible-in-sulfur sodium polysulfide (Na_2S_5 to Na_2S_3) products of the reaction of Na^+ ions from the electrolyte with the sulfur [2]. Because sulfur is an electronic insulator, the reaction of the Na^+ ions with the sulfur occurs at the surface of a carbon felt introduced into the sulfur to bring electrons to a large carbon–sulfur interface area. The negative post of the battery is attached directly to the molten sodium contained in a ceramic-electrolyte tube that is closed at one end and open to a molten-sodium reservoir at the other end; the reservoir keeps the Na^+ -ion electrolyte covered with Na throughout a discharge. The sulfur with its carbon felt bathes the outside of the ceramic-electrolyte tube, the carbon felt contacting a metal container to which the positive post is attached. The critical component of the cell is the Na^+ -ion ceramic electrolyte.

The Na^+ -ion electrolyte for a Na–S battery needs to consist of a framework host with mobile Na^+ ions in the

interstitial space, but it must also have the bottom of the conduction band of the host above the E_{FA} of elemental Sodium. These criteria are met in the Na- β and Na- β'' aluminas; but their frameworks have a 2D interstitial space and, therefore, an anisotropic thermal expansion. This anisotropic property is undesirable for a polycrystalline, thin ceramic membrane that is subject to repeated thermal cycling between room temperature and 350°C. Nevertheless, ceramic engineering of mixed β and β'' aluminas has resulted in a viable Na–S battery for stationary electrical-energy storage [25].

Stoichiometric Na- β alumina, $\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$, contains $\text{Al}_{11}\text{O}_{16}$ spinel slabs perpendicular to the [111] axis; the slabs are connected by oxygen bridges within intervening NaO planes containing intersecting 1D tunnels occupied by the Na^+ ions. In stoichiometric Na- β alumina, there are two inequivalent Na^+ -ion sites in the NaO planes, one of which is occupied and the other empty. The inequivalence of the Na^+ -ion sites raises the activation energy ΔH_m for Na^+ -ion motion, but the introduction of excess Na^+ either in $(1+x)\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$ or by substituting some Li^+ or Mg^{2+} for Al^{3+} in the spinel blocks reduces ΔH_m in the β phase; in the β'' phase, the Li^+ or Mg^{2+} substitutions shift the spinel slabs relative to one another to make equivalent the Na^+ -ion sites in the NaO layers, thereby reducing ΔH_m . A two-phase mixture of β and β'' phases with excess Na^+ ions gives a viable ceramic membrane.

The ZEBRA cell, which is under development by the General Electric Co., uses a molten-sodium anode and a solid β, β'' -alumina solid electrolyte as in the sodium–sulfur cell, but the positive electrode is large-surface-area nickel rather than molten sulfur with a large-surface-area current collector. The electrolyte on the cathode side of the ZEBRA solid electrolyte is an aqueous NaAlCl_4 containing NaCl and NaI as well as a little FeS. The FeS and NaI are added to limit growth of the Ni particles and to aid the overall cathode reaction, which is

on charge and on discharge

at a $V_{\text{OC}} = 2.58$ V. A *Lithium–Sulfur* battery also uses a sulfur cathode; its redox reaction is

Battery Components, Active Materials for. Figure 21
Schematic of a sodium–sulfur cell

in which the electrons from the anode on discharge are brought to the reaction by carbon [26]. The two-phase reaction proceeds in two steps, first to the polysulfides Li_2S_8 , Li_2S_4 , and Li_2S_2 at 2.4 V and then to Li_2S at 2.0 V. Best results to date have been obtained with a CMK-3 carbon impregnated by sulfur and electrolyte. The CMK-3 carbon consists of carbon nanorods kept apart by carbon bridges to give channels into which molten sulfur is introduced. On solidification, channels are opened for the impregnation of electrolyte to give Li^+ ions access to a large surface area of amorphous sulfur. The cathode reaction is relatively slow, and the efficiency of electrical-energy storage is not optimal. Nevertheless, the lower power density and the low voltage are compensated by a capacity of over 1,000 mAh/g. The low voltage requires use of a Li^0 anode. A protected Lithium anode (see Lithium/seawater battery) is a logical candidate for this battery, but a soluble Li_2S_n shuttle molecule may suppress build-up of the dendrites on the Li^0 anode. The jury is still out on whether this battery will be competitive for a low-power application.

Lithium–Metal Salt secondary batteries are analogous to the Lithium–seawater primary battery [3]. A Li^+ -ion solid electrolyte separates a nonaqueous anolyte and an aqueous cathode. For example, a Lithium anode with a carbonate anolyte and an aqueous $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$ cathode has been shown to give a flat voltage $V \approx 3.4$ V with an efficiency that increases with the molar ratio of iron cyanide in the cathode solution [27]. This promising approach requires development of a Li-ion solid electrolyte having a $\sigma_{\text{Li}} > 10^{-4}$ S/cm at room temperature that is stable to an acidic cathode solution and is not reduced by contact with a Li^0 dendrite on the anode side.

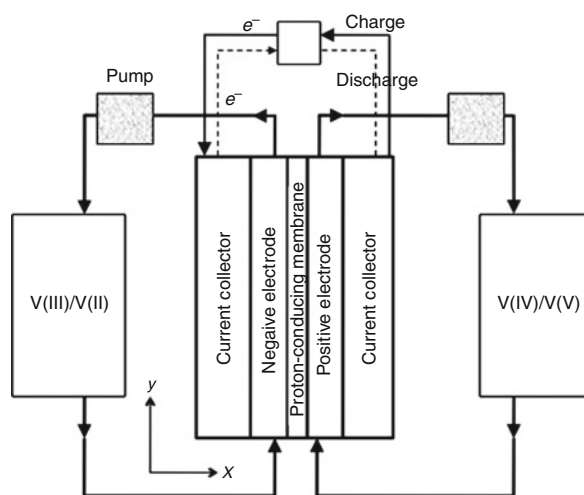

Lithium–air batteries [28] may also use a solid separator that will block dendrite growth from the anode to the cathode but allows permeation of the Li^+ ion between an anolyte and a catholyte. The simplest such separator would be a solid Li^+ -ion solid electrolyte, but a porous glass containing the liquid electrolyte has been used where the anolyte and the catholyte are identical. As in the Zn–air primary battery, a porous carbon containing an oxygen–reduction catalyst on the pore walls and the liquid electrolyte in the pores provides the structure needed to facilitate the catalytic reaction of

Li^+ ions with the gaseous O_2 cathode. The cathodic reaction

is reversible, but the voltage difference between charge and discharge currents is large even with the best catalyst, Pt–Au nanoparticles [29], which makes the battery inefficient for electrical-energy storage.

The **Redox-Flow Battery** [30] is a candidate for medium- and large-scale electrical-energy stationary storage. The cells of these batteries contain different redox energies in a liquid anode and a liquid cathode separated by either a solid electrolyte or a microporous polymer or glass separator. Reversible electrode processes take place at the surface of graphite-felt current collectors as in the sulfur cathode of a Na–S cell. The reactant redox couples flow across the carbon-felt conductors, entering the electrochemical cell from external reservoirs, Fig. 22. In theory, the capacity of a cell is determined by the volumes of the two electrolyte tanks. Under development is a cell containing vanadium ions in sulfuric-acid solution. The anode compartment contains V^{2+} ions, the cathode compartment VO_2^+ ; the cell reactions are

Battery Components, Active Materials for. Figure 22
Schematic of the all-vanadium flow-through battery

to take advantage of the 1.65 eV difference between the V(III)/V(II) and V(V)/V(IV) redox couples. Alternative couples include, for example, $\text{Fe}^{3+}/\text{Fe}^{2+}$ and $\text{Cr}^{3+}/\text{Cr}^{2+}$. These cells can achieve 80–90% energy-storage efficiencies in large installations at a low cost per kWh. They promise a long cycle life, are relatively easy to maintain, and can be fully cycled without harm to the battery. However, in order to realize the commercial potential of these batteries, several challenges must be met, including development of electrodes resistant to oxidation in its electrolyte, membrane stability and prevention of redox crossover through the separator membrane while maintaining a fast H^+ -ion transport across the membrane, easier flow across the current collectors, and scale-up optimization.

Future Directions

The Li-ion battery has already introduced the wireless revolution by powering the cell telephone and the laptop computer as well as their derivatives. Modest increases in anode capacity will improve the volume energy density for handheld electronic devices.

The Li-ion battery is also powering portable electric-power tools and small electric vehicles. However, its widespread application to the plug-in hybrid electric vehicle and the all-electric vehicle will depend on lowering the cost while increasing the driving range between recharges. To reach this target, it will be necessary to develop new cathode strategies. These strategies appear to depend on the development of a suitable solid electrolyte and sealants that can prevent crossover of different liquid electrolytes either side of the solid electrolyte.

Electrical-energy storage in batteries for the grid for increasing the efficiency of nuclear energy and for enabling the large-scale introduction of wind and solar energy will probably need the much larger capacities offered by flow-through batteries. In the interim, rebirth of the Na/S battery may provide some large-scale electrical-energy storage.

Realization of the great societal benefits to be derived from the new battery technologies has galvanized an extensive research activity that promises continued development.

Definition of the Subject

The demand for high performance and long life storage systems has lead to numerous research initiatives, aimed at the development of such systems. Developmental paths are aligned with the requirements of the applications of these systems. A detailed understanding of technical characteristics and cost considerations is provided in this paper for various battery chemistries: contemporary, vintage, and prospective. A clear understanding of battery characteristics is essential for guiding the selection of such batteries. Indeed, because of the critical functions fulfilled by batteries as well as the substantial costs of advanced batteries, a realistic appraisal of candidate battery performance and costs against requirements is key to judging the prospects of new applications such as EV, HEV, and plug-in hybrid electric vehicles (PHEV). Although electric vehicles (EVs) have been around since before 1900 the limitations of the batteries to drive them have not enabled them to compete in the general consumer's market with the internal combustion engine. Automotive parts are limited by space and weight. Therefore EVs and hybrid electric vehicles (HEVs) require a battery with high energy density. Specific energy is defined as the energy per kilogram of the battery while energy density is the energy per unit volume. Early designs (1990–1995) of lithium-ion batteries only had a specific energy of 0.2 kWh/kg. EVs also require a battery with high power output for large power draw, such as quick acceleration. The General Motors EV1 had a battery pack weighing almost 600 kg while the car weighed 1,350 kg. The battery would then account for more than 44% of the car's weight. A marked improvement in energy cell density of batteries was required for practical EVs.

Introduction

Basic Characteristics of Batteries

Introduction

In this paper, the first section covers the relationship between the internal resistance of the cell, maximum power output, energy efficiency in charging and discharging, and reduction of cell heating. This is followed by a review of the characteristics of lead acid, nickel metal hydride, lithium-ion batteries, and supercapacitors.

Recent advances in power electronics provide competitive performance for electric cars so they provide the necessary acceleration for wide spread adoption [1]. However batteries still lack the energy density of gasoline or diesel fuels and thus cannot compete in terms of the overall range that can be driven between recharging. Additionally, recharging may be slow. However, ongoing research and improvements in manufacturing may reduce both energy density limitations and costs. Concerns about greenhouse gases and other air pollutants are the other driving factors for the renewed interest in EVs and HEVs, which may reduce or eliminate the emission of NO_x , CO_2 , and hydrocarbon pollution from mobile vehicles depending on how the electricity used to charge the battery was generated. EVs and HEVs also reduce noise levels when running on electric mode. In 2009, 1.6 million HEVs were registered in the USA [2].

This section concentrates on a variety of battery technologies that have shown significant promise for long life and high performance. A brief, generic list of battery characteristics are provided in section “[Electrical Modeling for Batteries](#)”. Section “[Lead Acid Batteries](#)” introduces various types of lead acid battery chemistries. Section “[Nickel Metal Hydride Battery](#)” introduces the nickel metal hydride chemistry, while lithium-ion is discussed in section “[Lithium-Ion Batteries](#)”. The upcoming technology of supercapacitors is also introduced and a comparison to conventional electrochemical counterparts is provided.

This entry first gives a general overview of characteristics of batteries, followed by the electrical modeling used for batteries in EVs and concludes by presenting the different battery technologies used today.

Basic Characteristics of Batteries

An electrical battery is a power source composed of one or more electrochemical cells which convert stored chemical energy into electrical energy. In this section,

rechargeable batteries which can be used multiple times is discussed. A battery is composed of one or more electrochemical cells, each consisting of two electrodes and one (or two) electrolyte-containing anions and cations.

Figure 1 depicts the typical electrochemical cell voltage behavior during charging (labeled “Charge curve V”) and discharging (labeled “Discharge curve V”). Cell voltage drops and rises during discharging and charging respectively, in proportion to the cell’s internal voltage. The difference between the terminal open-circuit voltage and the discharge and charge voltage is attributed to the cell’s internal resistance. An ideal cell provides constant terminal voltage until empty. The internal resistance of real cells prevent ideal performance during discharge resulting in lower terminal voltage.

The essential characteristics of batteries are maximum power output, charging/discharging efficiency, and temperature effects. These are key factors to be considered when designing or choosing batteries for particular applications. These characteristics are further elaborated for each battery in the device specific sections of the paper. The basic definitions are shown below.

Maximum power output: A lower limit is set for each cell’s voltage. The maximum dischargeable current value is determined such that the cell voltage does not fall to this limit. The maximum current is determined as

$$I_{\max} = (\text{Open Circuit Voltage} - \text{Lower Limit Voltage}) / \text{Internal Resistance}$$

Then, maximum power output of a cell can be calculated as $P_{\max} = I_{\max} \bullet (\text{Open Circuit} - \text{Lower Limit Voltage})$. High power output requires low internal cell resistance.

Charging/discharging efficiency: Electrical energy transferred during a charging/discharging cycle can be computed as

$$E = \Delta Q \bullet V$$

where ΔQ is the transferred charge and V is the terminal voltage at that time.

In Fig. 1, the *area* between the charge curve and the horizontal axis is the total electrical energy transferred to the battery. Accordingly, the area between the discharge curve and horizontal curve is the total energy

Battery Technologies. Figure 1

Cell voltage profile and internal resistance in charging and discharging operations with respect to cell charge Q [3]

drained from the battery. Battery efficiency is a ratio of discharge to charge energy values. It is imperative to reduce the difference between these two curves to improve battery efficiency.

Temperature effect: Charging and discharging cycles can cause a cell's temperature to rise. For lithium-ion cells, operating temperatures above 50°C can lead to cell degradation. Ozawa [4] attributes the difference in charging and discharging curves in Fig. 1 to heat lost due to different operating temperatures. To suppress this difference, the cell's internal resistance must be reduced.

Electrical Modeling for Batteries

A simple model of a battery can help alleviate issues of understanding of a battery's behavior. The simplest electrical equivalent model of a cell is a voltage source with a resistor in series, as shown in Fig. 2a. This is the

internal resistance of the cell. Davide [5] provides corresponding voltage and current response curves for each proposed model.

A more complex model is described in Fig. 2b. This model emulates the behavior of a battery when instantaneously loaded. The initial voltage drop across battery terminals is small, due to R_1 . The voltage then drops exponentially to the level of both resistances with a time constant $T = R_2 \cdot C_2$ (~ 1 min). This phenomenon is known as relaxation.

A variation on 2b is 2c, where the time constant $T = R_3 \cdot C_3$ is ~ 1 ms. This model correctly emulates AC impedances on the order of 1 kHz. This property can however be misleading to the user since such impedances are usually measured with no load by the manufacturer. The user may also misread this impedance as the cell's DC resistance. Figure 2(d) combines 2(b) and 2(c) and thus equally satisfies both the manufacturer and the user.

Internal resistance of a cell results from a series combination of resistances due to bulk metal, chemical processes, and terminals. Varying loads can have dynamic effects on these properties of a battery. Thus the battery’s internal resistance (R_i) also has dynamic properties. Davide explains that internal resistance can vary with the following battery characteristics:

State of charge:	R_i is high for both high and low state of charge levels
Temperature:	R_i is higher at cold temperatures
Current:	R_i is higher at higher currents when charging (compared to the same current when discharging)
Usage:	R_i increases over time with cell usage

Figure 3 shows how the internal resistance of a lithium iron phosphate (LiFePO_4) battery varies versus the above four battery characteristics.

For preliminary research purposes, it is entirely possible to create a generic model and vary key parameters to simulate the performance of various battery chemistries. Table 1 provides a list of key parameters for

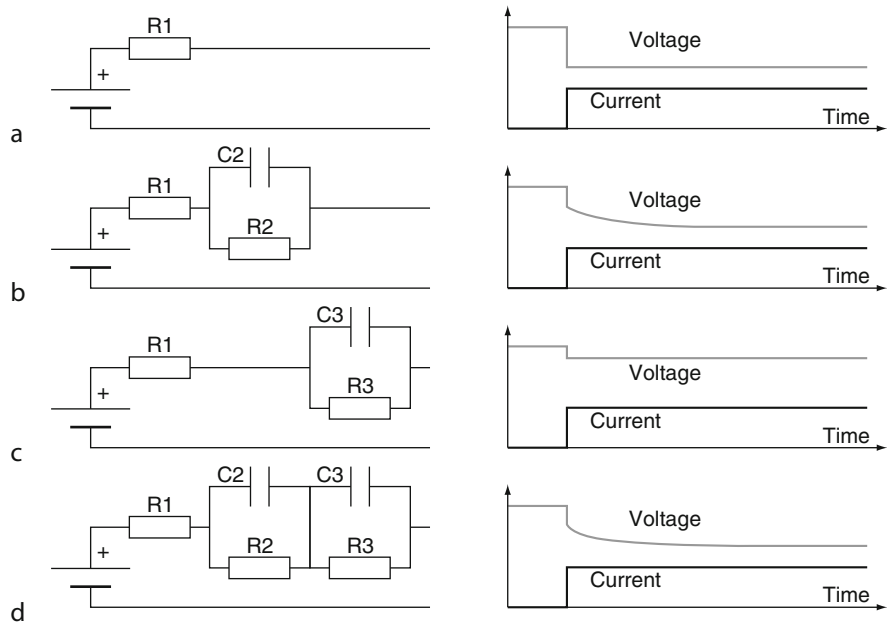

three batteries chemistry as well as three types of supercapacitors.

Detailed reviews of various battery chemistry compositions are provided in the following sections. We consider not only relevant chemical reactions, but also applications, cost, and efficiency concerns associated with every chemistry type. The following section details lead acid batteries, their cell construction, and the electrochemistry, for several types of lead acid batteries used in EVs and their characteristics.

Lead Acid Batteries

Lead acid (PbA) batteries are inexpensive and have characteristics somewhat suitable for energy storage in EVs. Design is possible for short, high-rate discharges or for bulk energy storage. These batteries are commonly used to power the starter motor of conventional internal combustion engines.

Lead acid batteries are classified into two broad categories, traditional vented lead acid (VLA) batteries and valve-regulated lead acid (VRLA) batteries. The latter have dominated the stationary battery market over the past 20 years [1]. VRLA batteries have immobilized electrolyte and a means to recombine

Battery Technologies. Figure 2

AC impedance time constant (s)	10 ⁻¹ –10 ⁻³	10 ⁻¹ –10 ⁻³	10 ⁻³	N/A	N/A	N/A
Recommended operating temperature (°C)	25	–20 to 50	50	–25 to 85	–40 to 85	–30 to 70

charged gas, thus conserving water in the cell. They are typically smaller than their vented counterparts and require less maintenance. Most of the VLA and VRLA batteries use pasted plate construction, in which a mixture of active materials is pasted onto lead alloy grids. The characteristics of the final battery are heavily influenced by the alloy composition. Tubular plate construction is also quite common, in which the active material is held in non-woven fibrous tubes with a center conductor of lead alloy.

Lead acid batteries have less energy density and specific energy as compared to the more recent lithium-ion and NiMH batteries but these batteries generally have high ampere rating. Since lead acid batteries

do not have the deep cycling capability and energy density compared to other batteries used in EVs, they are being replaced by NiMH and Li-ion batteries for traction purposes. However earlier EVs used lead acid batteries like the GM EV1 (Generation 1). The Delphi 704 VRLA-Prismatic battery has an ampere rating of 53 Ah and a specific energy of 35.3 Wh/kg. These batteries have a good cycle life of 15,000–30,000 cycles. In the following section, the cell construction and electrochemistry of lead acid batteries are discussed [4].

Cell Construction and Electrochemistry

All lead acid designs share the same basic chemistry. The positive electrode (cathode) is formed of porous lead

Battery Technologies. Figure 4
Charging lead acid cell schematic [3]

dioxide (PbO_2) while the negative electrode (anode) is composed of sponge lead (Pb). Sulfuric acid (H_2SO_4) in water serves as gelled electrolyte between the two electrodes. Lead dioxide at the cathode is supported by a thin lead grid. Figure 4 provides a cross-sectional view of a standard lead acid battery cell.

Pure lead is generally too soft to be used as a plate material and usually requires addition of an alloy. Alloy candidates vary and are responsible for positive plate subtypes such as lead-antimony, lead calcium, and pure lead. Lead-antimony cells are recommended for applications requiring very long life and discharging to depths greater than 20% of rated capacity. Pure lead cells are recommended for float and shallow cycling service where average discharge depth is less than 20%. Finally, pure lead alloy cell types are used when very low charged stand loss is a requirement in the application and occasional deep cycles are expected [6].

During charging, as the cell approaches full charge, a majority of the PbSO_4 is converted to Pb and PbO_2 . Beyond this point and under high charging voltages, cell voltage becomes greater than the gassing voltage (about 2.39 V per cell) and the overcharge reactions begin. This results in the electrolysis of the water contained in the electrolyte, and the production of hydrogen and oxygen. In sealed lead acid cells, this

reaction is controlled to minimize hydrogen evolution and loss of water by recombining evolved oxygen with the negative plate.

The discharge chemical reactions are as follows:

As the cell discharges, lead at the anode reacts with hydrogen sulfate ions to form lead sulfate, along with hydrogen ions and electrons. These electrons then travel through the external circuit. Note that sulfuric acid is a strong electrolyte and breaks down into hydrogen and hydrogen sulfate ions even before being placed in the battery. This breakdown is independent of the battery plates. At the cathode, lead dioxide is reduced by the two electrons released at the anode and the lead ion then reacts with sulfate to form lead sulfate along with water. Discharge continues until all of the sulfuric acid is converted to water. Discharging is an exothermic process and charging is an endothermic process.

As discharging progresses, the concentration of the sulfuric acid electrolyte falls. As a result, the no-load (open circuit) voltage of a lead acid cell varies during a cycle from approximately 2.1 V at the top of charge to approximately 2 V at the bottom of discharge. In addition, the decreasing concentration of electrolyte leads to an increasing internal resistance that reduces overall efficiency of the cell. All these factors come together to signify for a given current, the terminal voltage of a lead acid cell is lower at the end of discharge than at the beginning [3].

Lead is insoluble and stays at either plate during charging or discharging. This property allows recharging of the battery. In contrast, non-rechargeable batteries contain reaction products that either convert to an insoluble precipitate or are lost as gas.

Two side reactions can occur in lead acid cells, primarily at the top of charge: hydrogen production from the lead negative plates and oxygen generation from the lead dioxide positive plate. In flooded cells, these side reactions lead to a loss of water that must be made up periodically. The loss of water is particularly high during overcharge and equalization of batteries of

cells, which must be performed each full charge and once every 10 or 20 cycles, respectively. Overcharge and equalization both involve charging the lead acid cells somewhat beyond the ampere-hour capacity that has been discharged, so as to ensure that all the electrodes of all the cells of the battery are fully and equally recharged [3].

The next section gives a brief description of the different types of lead acid batteries.

Types of Lead Acid Batteries (by Electrode Material)

Lead Calcium Batteries Lead acid batteries with electrodes that are modified by the addition of calcium are more resistant to corrosion, overcharging, gassing, water usage, and self-discharge. All of these factors shorten the life of a battery. The increased resistance increases the battery life of lead calcium batteries. Additionally, they have a larger electrolyte reserve area above the plates, higher cold cranking ampere ratings, and require little maintenance [4].

Lead-Antimony Batteries Lead acid batteries with electrodes modified by the addition of antimony improve the mechanical strength of electrodes which is important for EV and deep discharge applications. Water loss and the internal heat are also minimized. They have a longer life than lead calcium batteries. These batteries are also easy to recharge when they are completely discharged and are comparatively less expensive compared to other types of lead acid batteries. However, lead-antimony batteries have a higher self-discharge rate typically 2–10% per week, whereas lead calcium batteries have a self-discharge rate of 1–5% per month [4].

Advanced Lead Acid Batteries In the early part of the decade, the lead acid battery community formed the Advanced Lead–Acid Battery Consortium (ALABC) in a concerted effort to make electric vehicles a reality by overcoming the shortcomings of the VRLA battery. Much has been achieved by the global research and development program of the ALABC [7].

The ALABC originally developed advanced lead acid batteries as a replacement for the more expensive NiMH batteries used in hybrid electric vehicles. These advanced lead acid batteries exhibit better performance as compared to VRLA batteries, in terms of stationary

energy storage [8]. Some of the results of research in advanced lead acid batteries are discussed below.

Swelling of the positive active material in the direction normal to the plane of the plate remains a serious concern for VRLA batteries. The tendency for the positive active material to expand with repeated deep cycling is, however, beyond dispute. Experimental work at the University of Brno demonstrated a clear correlation between loss of capacity with cycling and increase of active-material resistance which is presumed to arise as a result of swelling [7].

An in-depth study of positive-grid alloys demonstrated that the introduction of tin brings additional benefits in the form of enhanced corrosion resistance and reduced electronic resistance. Positive grids that contain no antimony but have 1–1.5% by weight of tin do not suffer expansion in the plane of the plate and as a result of the lower corrosion rate, it is possible to contemplate a substantial reduction in grid thickness and weight in order to increase the specific energy [7].

Also, the ALABC development work discovered that adding a small amount of carbon (2–4% by weight) to the negative active material of the electrode minimized negative plate sulfation and enhanced VRLA battery cycling performance in partial-state-of-charge cycling. Battery developers/suppliers who are currently involved in research and development of advanced lead acid batteries include East Penn, North Star, Exide technologies, Axion Power, and Furukawa [8].

Types of Lead Acid Batteries (by Construction)

Flooded/Vented Lead Acid Batteries These batteries have electrodes or plates which are immersed in the electrolyte. The level of the electrolyte reduces as a result of charging and the gases formed which are vented to the atmosphere, so distilled water is added to bring the electrolyte back to its initial level. The most familiar example of a flooded lead acid cell is the 12 V automobile battery.

Valve Regulated Lead Acid (VRLA) Batteries VRLA batteries are also called sealed lead acid (SLA) batteries. They are designed to prevent electrolyte loss through evaporation, spillage, and gassing, which in turn prolongs the life of the battery and reduces maintenance cost. Instead of simple vent caps on the cells to let gas

escape, VRLA batteries have pressure valves that open only under extreme conditions. Hydrogen and oxygen are generated by galvanic action of the battery during charging. VRLA batteries need an electrolyte which reduces gassing by impeding the release of these gases to the atmosphere. A catalyst is usually involved that causes the hydrogen and oxygen to recombine into water. This system is called a recombinant system. Since acid electrolyte spillage is eliminated, these batteries are safer [4]. There are two categories of VRLA batteries.

Types of VRLA

AGM (Absorbed Glass Mat) Batteries AGM batteries are similar to VRLA batteries. A boron silicate fiberglass mat acts as a separator between the electrodes and absorbs the free electrolyte. The main purpose of this type of battery is to recombine the hydrogen and oxygen generated during the charging process. The fiberglass mat absorbs and immobilizes the electrolyte, but keeps it in a liquid rather than a gel form. In this way, the electrolyte is more readily available to the plates allowing faster reactions between the electrolyte and the plate material which gives higher charge/discharge rates as well as deep cycling capability. AGM batteries are very robust and can withstand severe shock and vibrations. Also, the self-discharge rate is low, typically 0.25–0.75% per month. They are also called “starved electrolyte” or “dry” batteries because the fiberglass mat is 95% saturated with the electrolyte and there is no excess liquid [4].

Gel Cell The gel cell is similar to the AGM battery, except that the electrolyte is gelled to immobilize it. The electrolyte is mixed with a silica compound to create the gelled solution. It uses an alternative recombinant technology to promote recombination of the gases produced during charging. It also reduces the possibility of spillage of the electrolyte. Charging rates are limited, because overcharging may cause excess of gases to be released causing damage. The gel cell cannot be fast charged on a conventional automotive charger since it can cause permanent damage [4].

Choosing a Battery

The ideal EV battery should have a constant output voltage at any value of current drawn over the entire state-of-charge (SOC) range and it should also accept

high charge rates at the same voltage. No battery has such ideal characteristics but the suitability of a battery for EV use can be determined by the ratio of charging voltage to discharging voltage over the range of SOC and current [9].

Given below are the important factors to consider while choosing a battery for EV use.

Power Battery power performance is generally specified by manufacturers as W/kg at either 2/3 or 1/2 of the open circuit voltage. This ignores the ratio of the terminal voltage under load to that during charge or regenerative braking which is the relevant parameter for EV applications. A more useful figure of merit for comparing the power performance of EV batteries is the power density (W/kg) at 75% end-of-charge voltage (V_{eoc}). For example, if the battery voltage of an EV drops below 75% of V_{eoc} during acceleration, it means that the battery is operating at low cycle efficiency. Another consideration is the cost of the vehicle drive train which is proportional to the product of the maximum voltage rating and the current rating. A low power battery needs more expensive drive train components to achieve a given level of performance because it needs higher current to extract the same power at a lower voltage. A high power battery not only increases vehicle performance but it reduces the cost of the motor and electronics for equivalent performance.

Energy Energy capacity of an EV battery determines the vehicle range. The two parameters which are commonly used to specify energy capacity are specific energy and energy density. Reducing energy consumption is often a better way to increase EV range than increasing battery capacity. EV batteries cannot yet match the energy density of gasoline but provide power to exceed the acceleration of conventional vehicles. One of the unique features of EVs is the capability to provide high peak power and excellent acceleration without sacrificing operating efficiency [9]. The Tesla Roadster sports car demonstrates this by operating at 180 Wh/mile in normal driving and offering acceleration from 0 to 60 mph in 3.7 s, which is quicker than a gasoline-powered Mercedes-Benz SLR McLaren. The first-generation EV1 used Delphi's valve-regulated lead acid batteries, which is capable of operating at 164 Wh/mile. Nickel metal hydride batteries (NiMH)

batteries (See section “[Nickel-Cadmium Battery](#)”) have twice the energy density and specific energy compared to lead acid batteries. An EV fitted with a NiMH battery which is of the same size and weight as a lead acid battery has twice the range. However, due to power considerations, it is not necessary that an EV could be built to match the range of a lead acid battery powered EV using a NiMH battery with half the size and weight [9].

Cost Although lead acid batteries have less energy density and specific energy and are bulkier compared to NiMH and lithium-ion batteries, they are typically inexpensive. Today, a lead acid battery pack for an EV costs \$215/kWh, a NiMH battery costs \$350/kWh, and a lithium-ion battery costs \$400/kWh [9]. The lower cost of the lead acid battery makes it an affordable technology and also decreases the overall cost of EVs. Axion Power, a firm based in Pittsburgh, Pennsylvania, has come up with a new technology called lead-carbon battery which is derived from traditional lead acid battery technology. Axion Power has managed to convert a pickup truck to run on a pack of the lead-carbon battery for around \$8,000 [10]. If further cost reductions are achieved in the production of batteries, then EV pricing can become competitive with conventional vehicles.

Temperature Effects on Batteries Batteries function because of electrochemical reactions (charging and discharging) taking place in the cell. These chemical reactions are dependent on temperature. Nominal battery performance is usually specified for working temperatures between 20°C and 30°C. However the actual performance can deviate substantially if the battery is operated at higher or lower temperatures. The operation of any battery generates heat due to the I^2R losses as current flows through the internal resistance of the battery whether it is being charged or discharged. This is also known as electrical heating or Joule heating. During discharge, since the total energy within the system is fixed, the temperature rise is limited by the available energy. Another factor which affects the performance of a battery is the ambient temperature. If the ambient temperature is higher than the temperature of the battery, the battery gains heat from the surrounding

and if the ambient temperature is lower, the battery losses heat to the surrounding. The difference in the ambient and the optimal operating temperature of a battery reduces its performance. Overheating may also be caused in batteries because of highly exothermic reactions, which generate a lot of heat and may ultimately damage the batteries [4].

Lead acid batteries are exothermic during charging, which makes their temperature rise dramatically. If the temperature exceeds beyond a limit, the battery may be damaged. Also, being a galvanic cell, its internal resistance is temperature dependent. Internal temperature decreases as the temperature rises due to the increase in electron mobility. The cell is very inefficient at low temperatures but the efficiency improves at higher temperatures due to the lower internal impedance and also because of the increased rate of chemical reactions. However, the lower internal resistance also causes the self-discharge rate to increase. Additionally, the cycle life deteriorates at high temperatures. Some form of heating and cooling is therefore required to maintain the battery within a specific temperature range to achieve optimum performance [4].

Life Battery life represents an important parameter in battery performance that affects customer satisfaction and overall cost. Battery life depends mainly on the number of cycles. Technical factors such as temperature control, charging procedures, and exposure to abusive conditions also play an important role in determining the battery life. Lead acid batteries in EVs may last 15,000–30,000 cycles if used regularly. However, they start deteriorating after 2 years regardless of the kind of use. Lead acid batteries respond well to battery management systems that control temperature and maintain SOC equalization. A factor related to battery life is the battery residual value. Although virtually all EV batteries are recycled for economic and environmental reasons, EV batteries may retain value greater than their salvage value after their useful life as a traction battery is complete. AC Propulsion regularly sells spent traction modules as starter batteries with a 2-year warranty for \$25 or about \$50/kWh. These modules are retired because their capacity is diminished by 30% or more, but they serve well as starter batteries [9].

Table 2 below shows some typical specifications of VRLA batteries used in EVs.

Battery Technologies. Table 2 Specifications of VRLA batteries in EVs [11, 12]

Electric vehicle	1998 Ford Ranger EV	GM EV 1, first model
Manufacturer	Delphi	Delphi
Number of modules	39	26
Weight of module (kg)	19.3	18.8
Nominal module voltage (V)	8	12
Nominal system voltage (V)	312	312
Nominal capacity (Ah)	60 (100% capacity)	53 (50% capacity)
Specific energy (Wh/kg)	23.7–25.2	26.3–31.9
Efficiency (Wh/mile)	237–356	115–164

Lead Acid Battery Circuit Model

Consider Fig. 5 as a lead acid cell model. We construct this circuit using PSpice software. Consider the cell to provide 2 V nominal voltage, 10 Wh capacity, round-trip efficiency of 90%, and 70% initial state of charge. Here, available energy during operation is computed as

$$\text{SOC}(t) = \text{SOC}_{\text{initial}} + \frac{1}{\text{Capacity(Wh)}} \int \frac{kV_1 I_{\text{bat}}}{3600} dt$$

where k is cell efficiency, V_1 is cell voltage, and I_{bat} is cell current. During discharge, current flows in the opposite direction when compared to charging, leading to a minus sign before the integral. Division by 3,600 is needed to ensure that cell capacity is in units of watt-hours, Wh. Alternate charging and discharging operation is conducted by applying AC current I_{AC} at 4 A, 100 Hz, as shown in Fig. 16. Resistor R_1 is chosen arbitrarily high to ensure there is no voltage drop at the cell's output terminals.

Figure 6 shows the state of charge (SOC) of the cell.

Note that the Y-axis provides state of charge as a percentage. Figure 7b provides cell voltage V_1 , whereas I_{AC} is shown in 7a.

Note that in addition to the nominal 2 V, cell voltage is a function of state of charge of the cell. For example, a certain degree of overvoltage can occur with high state of charge. A 70% state of charge leads to a cell (over) voltage of 2.1 V in 7b.

Battery Technologies. Figure 5
Lead acid cell model using PSpice

When I_{AC} is positive, current travels into the cell, simulating charging. This is evident in Fig 18b where V_1 drops while I_{AC} increases in the positive direction. Negative I_{AC} implies cell discharge, with V_1 above the nominal 2 V. An immediate advantage of lithium-ion batteries is their diversity in operation. Figure 19 shows only a few possible chemical combinations.

Nickel-Cadmium Battery

The nickel-cadmium battery commonly abbreviated as NiCd battery is a type of rechargeable battery which works by oxidizing nickelic hydroxide ($\text{Ni}(\text{OH})_2$) into nickelous hydroxide (NiOOH) and has metallic cadmium as electrodes. The charge/discharge reaction can be given as follows:

The features of this battery are that the electrolyte does not take part in any of the chemical reactions and the active materials are insoluble in the electrolyte. Nickel-cadmium batteries have a reputation for their robustness, reliability, and service life. They can also operate under severe weather conditions, with operating temperatures ranging from -40°C to $+60^\circ\text{C}$ (because the electrolyte has a very low freezing point), excellent cycling capability (up to 2,000 cycles at 80% depth of discharge), long storage life, and low or zero maintenance [10, 11].

NiCd batteries have been used extensively in consumer electronics and power tools. In the recent past, NiCd batteries have also been used in electric vehicles, an example being the Peugeot 106 electric, which used NiCd batteries manufactured by SAFT [12].

Nickel-cadmium cells have a nominal cell potential of 1.2 V. This is lower than the 1.5 V of many popular primary cells, and consequently they are not

Battery Technologies. Figure 6
Cell state of charge

Battery Technologies. Figure 7
Applied AC current and cell voltage

appropriate as a replacement in all applications. NiCd batteries have an energy density of 40–60 Wh/kg, which is greater than that of lead acid batteries, but less when compared to NiMH and Li-ion batteries [14].

Advances in battery-manufacturing technologies throughout the second half of the twentieth century have made batteries increasingly cheaper to produce; about 1.5 billion NiCd batteries were produced

annually up until 2000. NiCd batteries never became widely used as a replacement for lead acid batteries in the areas where those batteries dominate, mainly because of the toxic nature of the battery and the reduction in its capacity as the battery ages. However, NiCd batteries had an overwhelming majority of the market share for rechargeable batteries in consumer electronics up until the mid-1990s [10].

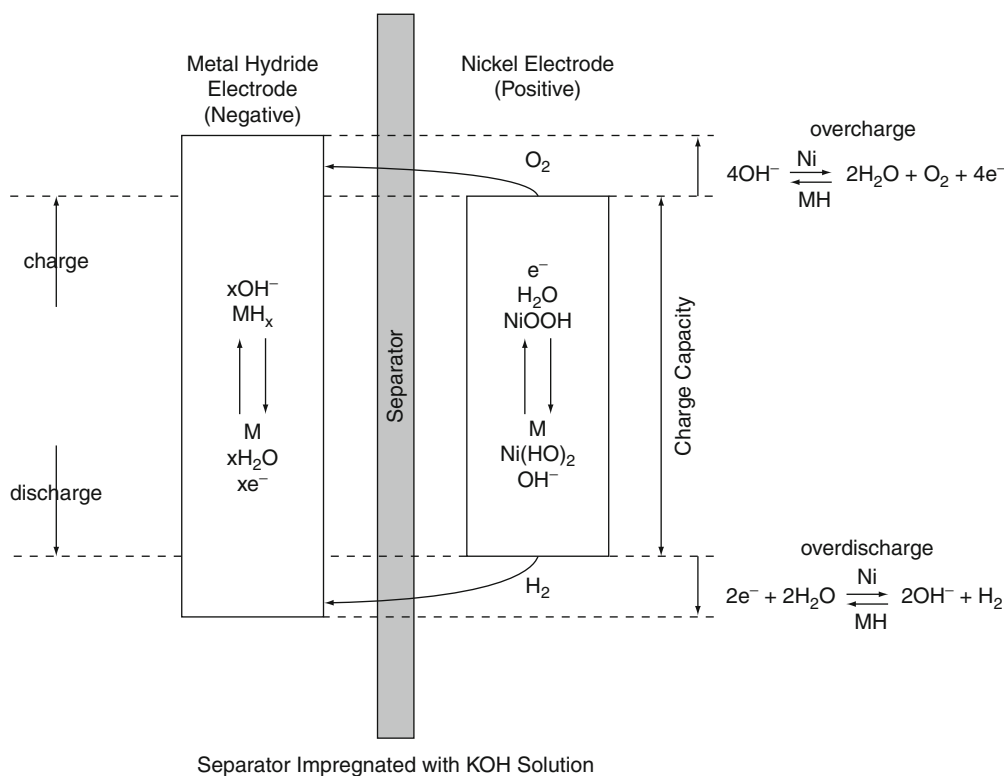

Nickel Metal Hydride Batteries

Nickel metal hydride (NiMH) batteries were first developed in the late 1980s and ever since have been used in portable electronic devices like camcorders, power tools, and cell phones. NiMH batteries have high storage capacity and relatively high ramp rates. They have succeeded lead acid batteries owing to higher number of cycles and higher energy density [14]. A study by EPRI in 2004 showed that NiMH batteries are acceptable for full-function EVs, city EVs, and plug-in hybrid electric vehicles (PHEVs) [8].

Although the technology was largely driven by military and government research in its earlier days, recently, significant contributions have been made by EV manufacturers. Applications of NiMH EV batteries include all PHEVs manufactured by General Motors, Honda, Ford, Toyota, and the Vectrix scooter, among others. The town of Nice, France, now operates its low floor tram, manufactured by Alstom using NiMH batteries. Honda's humanoid prototype robot ASIMO is another application.

Nickel Metal Hydride Cell Construction and Chemistry

The basic representation of a NiMH cell is shown in Fig. 8. The positive electrode of a NiMH cell consists of a spongy mass of nickel hydroxide $\text{Ni}(\text{OH})_2$. During charge, the positive electrode releases hydrogen into the electrolyte, which in turn combines with hydroxide (OH^-) ions. This reaction results in nickel oxyhydroxide (NiOOH) on the positive electrode and water (H_2O) in the electrolyte plus one free electron, e^- .

Battery Technologies. Figure 8

Schematic representation of a NiMH cell [7]

The equation for the positive electrode can be given by:

The negative electrode contains a metal alloy-hydride complex. In an exothermic reaction, the water (H_2O) from the electrolyte combines with the free electron to form metal hydride (MH) and hydroxide (OH^-). The metal alloy absorbs and desorbs the hydrogen, allowing the electrochemical reaction to occur without producing hydrogen gas. Equation 2 shows the net chemical reaction that occurs at the negative electrode during charge and discharge.

The most commonly used electrolyte is a solution of aqueous potassium hydroxide, KOH, in which the KOH concentration ranges from 25% to 40% by mass. The two equations show that there is no net change in electrolytic quantity. This result contrasts with other electrolyte systems like NiCd, where water is generated at both electrodes during charge and consumed at both electrodes during discharge. Although transient electrolyte concentration gradient occurs in NiMH batteries, its constant average concentration has good overall performance in gas recombination, kinetics, high and low temperature operation, and resistance to cycle life limitations caused by corrosion and swelling [7].

Overcharge and Over-discharge Reactions

The NiMH battery has overcharge and over-discharge reactions that allow the battery to handle abuse conditions of overcharge and over-discharge without adverse effects. The reaction that takes place at the two electrodes during overcharge is an oxygen recombination reaction. It can be shown as follows:

At the positive (Ni) electrode OH^- ions are oxidized generating oxygen:

At the negative (MH) electrode the oxygen is reduced:

The net result is generation of heat which is proportional to the energy input. This occurs at the expense of increasing the stored charge in the battery. If the rate of charge input exceeds the rate of recombination, the cell pressure increases, which may lead to cell damage.

During over-discharge, hydrogen is released at the positive electrode and recombined at the negative electrode. The reactions are as follows:

At the positive electrode, water is reduced and hydrogen gas is released:

The hydrogen gas is then oxidized at the negative (MH) electrode:

The ability of the NiMH cell to tolerate over-discharge is very important for large series strings of batteries since capacity mismatches may cause some cells to over-discharge. To ensure that the overcharge and over-discharge reactions function properly and thus control the buildup of cell pressure, the NiMH battery is constructed with the Ni electrode as the capacity limiting electrode and the MH electrode with excess capacity to allow recombination reactions to take place during overcharge and over-discharge [7].

Types of NiMH Batteries

The earliest pioneering work on NiMH batteries was performed at the Battelle-Geneva Research Center starting after its invention in 1967. These batteries showed high specific energy up to 50 Wh/kg, power density up to 1,000 W/kg, and a reasonable deep cycle life of 500 cycles (depth of discharge: 100%). Due to the inherent deep cycling capability and the high specific energy, NiMH batteries have been used in EVs. The two major types of NiMH batteries used today are the cylindrical batteries and the prismatic batteries. The next section describes the cylindrical NiMH batteries in detail giving the battery structure and the battery characteristics. The later section describes prismatic NiMH batteries and gives the comparison between the two of them. Currently, there are over two million HEVs running worldwide, which use NiMH batteries [15].

Cylindrical NiMH Cell

Battery Structure The single cell shown in Fig. 9 is a sealed cylindrical battery of D-size with a diameter of 32 mm and a height of 60 mm. A sealing plate is equipped with a valve to prevent bursting with an increase in internal pressure. The battery case is made of steel and both positive and negative electrodes are coiled and separated by a separator. This battery optimizes the reaction area of the electrodes, reducing resistance for current collection and improving electrolyte composition to obtain high power characteristics. The nominal battery capacity is 6.5 Ah and the maximum output power is more than 100 W per cell. To reduce the internal resistance and shield against vibrations, disk plates are inserted for cell connection [13].

Battery Characteristics Table 3 gives the characteristics of a single cylindrical cell and battery consisting of six cells.

Discharge Power Characteristics Figure 10 shows the specific power characteristics of a battery module that consists of six cells at different state of charge (SOC). The module provides 800 W in 2 s and 650 W in 10 s. As seen in the graph, for a given range of charge capacity, the specific power is almost constant. Also, for the 50% SOC and 100% SOC, there is not much variation in specific power, giving 650 W/kg in 2 s and 600 W/kg for a 10 s duration. Relatively constant input and output power is highly desired by EV manufacturers. It can be

clearly seen from the graph that NiMH prismatic batteries deliver an almost constant power for any SOC, which is highly desirable in batteries for EVs.

Charge Efficiency For practical use, high charge efficiency is required over a wide temperature range. Figure 11 shows the battery has a very high charge efficiency, which provides high regenerative acceptability over the SOC range, mostly used during normal vehicle operation. The ampere-hour charge efficiency is nearly 100%. Also because of the very small energy loss, heat generation of the battery is minimized.

Life Cycle Characteristics To preserve an active battery system, flow of power in and out of the battery needs to be maintained, even if minimal. The battery's

Battery Technologies. Table 3 Characteristics of a single cylindrical cell and battery consisting of six cells [13]

	Single cell	Battery module (six cells)
Output power	625 W/kg, 2,160 W/l	600 W/kg, 2,070 W/l
Input power	500 W/kg, 1,720 W/l	480 W/kg, 1,660 W/l
Energy density	45 Wh/kg, 172 Wh/l	43 Wh/kg, 161 Wh/l
Nominal voltage	1.2 V	7.2 V

controller needs to ensure that the battery is neither fully charged nor completely discharged. To test such operating conditions, a life test was conducted at Panasonic's test facility in Shizuoka, Japan. One example of the results is shown in Fig. 12 [13]. The test provides results in which the input and output power simulate real vehicle driving at 35°C. As a result, the durability was found to be equivalent to more than 100,000 km driving without deterioration of battery characteristics.

Prismatic NiMH Battery

Structure To improve power, reduce the number of connected parts. Figure 13 shows the appearance of a prismatic module design consisting of six cells in series. The conventional cylindrical module has connecting plates to connect cells and plastic insulating rings to prevent external short circuits. The prismatic module adopts internal connection; therefore, connecting plates and plastic insulating rings are not required. As a result, a shorter current path is accomplished. The investigation of electrode dimensions and current collector design shows that the current flow path is shortened. By thinning the positive and negative electrodes, the number of electrodes are increased, which increases the reaction area and decreases the current density. Resin material is used to make the battery case, which provides increased safety and reliability. The resin material makes it easy to design bumps and ribs on the side of the battery case. The bumps and ribs provide cooling and also reduce the pack volume by 40%. The resin also reduces 20% of the prismatic battery's weight compared to a cylindrical battery pack. The six cells are internally connected to form one module. External connection parts like bus bars and connecting plates are also not required [13].

Figure 14 shows the improved power characteristics and reduced internal resistance of this battery, as compared to the cylindrical battery. The main source of the

Battery Technologies. Figure 13

Prismatic NiMH battery [13]

Battery Technologies. Figure 14

Internal resistance of prismatic and cylindrical battery cell before activation [13]

reduction in internal resistance is the components. A high specific power of 1,000 W/kg, which is higher than that of the conventional cylindrical battery, is also achieved.

Table 4 shows the module characteristics of both prismatic and cylindrical battery types. It is clear that the prismatic design is superior to the cylindrical design.

Battery Technologies. Table 4 Comparison between prismatic and cylindrical battery modules [13]

	Prismatic module	Cylindrical module
Dimensions (mm)	19.6 × 106 × 275 (width × height × length)	35 × 384 (diameter × length)
Nominal voltage (V)	7.2	7.2
Nominal capacity (Ah)	6.5	6.5
Specific power (W/kg)	1,000	600
Specific energy (Wh/kg)	46	43
Weight (g)	1,020	1,090

Discharge Power Characteristics Figure 15 shows the power characteristics of the prismatic module at different SOC. This battery provides 1,000 W of power per kilogram for 10 s and 1,150 W of power for 2 s with the SOC maintained in a range 40–60%. It also has high power density at low SOC; about 800 W/kg for 10 s and 1,000 W/kg for 2 s at 20% SOC.

Figure 16 shows the power characteristics at different temperatures for the cylindrical battery and

Battery Technologies. Figure 15

Specific power of prismatic battery at different SOC [13]

Battery Technologies. Figure 16

Specific power of prismatic and cylindrical battery module at different temperatures [13]

the prismatic battery. As seen, the characteristics of the prismatic battery are better (490 W/kg at 0°C and 120 W/kg at -30°C). Also the temperature where power discharge of 200 W/kg is possible is reduced by about 10°C as compared to the cylindrical battery.

Life Characteristics of Prismatic Batteries In Fig. 17, Pattern A represents a normal driving profile, with a maximum SOC deviation of 15% and pattern B represents a high load driving profile with a maximum SOC deviation of 30%. After tests corresponding to a driving distance of 300,000 km with pattern A at 35°C, there was no deterioration observed in battery performance. Also, with pattern B at 55°C, the battery was able to achieve a driving distance of 200,000 km [13].

Figure 18, above, shows the EV-95 (95 Ah) and EV-28 (28 Ah) units developed by Panasonic for EVs. EV-95 has long life characteristics of more than 1,000 cycles and 4 years of onboard driving [13].

The batteries shown above have the following characteristics:

1. Optimization of additives (Y_2O_3) for excellent charge efficiency of the positive electrodes
2. $MnNi_5$ system of hydrogen-absorbing alloy for the negative electrodes
3. High performance, hydrophilic-treated polypropylene separator

Battery Technologies. Figure 17

Life cycle characteristics of prismatic batteries [13]

Battery Technologies. Figure 18
EV-95 and EV-28 batteries by Panasonic

The electrode groups consist of alternately stacked positive electrodes and negative electrodes interleaved with separators. Inserting these electrode groups into a resin battery case and sealing with a cover equipped with a valve after filling with alkaline electrolyte forms the cell. A battery module consists of ten cells connected in series by metal plates and these are configured to permit airflow between the cells to ensure a uniform temperature distribution.

Table 5 gives the characteristics of the EV-28 and EV-95 batteries manufactured by Panasonic.

Below is Table 6, which gives characteristics of NiMH batteries, produced by Texaco Ovonic Battery Systems and VARTA.

The second-generation GM EV1 used NiMH batteries. Table 7 shows the specifications of that battery.

Lithium-Ion Batteries

Lithium-Ion Battery Chemistry

Lithium is the least dense of all solid metals, has the greatest electrochemical potential, and provides the largest energy density by weight. For many years, lead acid had been the predominant battery for large-scale equipment. G. N. Lewis pioneered early work with lithium-ion battery technology but it was not until the early 1970s before it became commercially viable. Because of the inherent instability of lithium metal, early attempts at rechargeable batteries failed. Research then shifted to lithium-ion-based composites which, although less dense, are safer to use. Lithium-ion batteries emerged during the early 1990s. Today, lithium-ion is the fastest growing and most promising battery chemistry.

Battery Technologies. Table 5 Basic characteristics of the EV-28 and EV-95 batteries [13]

	EV-28	EV-95
Dimensions (width × height × length) mm × mm × mm	75 × 110 × 388	116 × 175 × 388

Nominal system voltage	343 V
Nominal capacity (50% charge capacity)	85 Ah

As mentioned earlier in section “[Basic Characteristics of Batteries](#),” a battery functions as a combination of chemical reactions, oxidation at the anode (where electrons are generated in discharge mode), and reduction at the cathode (at which electrons enter the cell). Depending on the direction of the current (charge or discharge) each electrode is either the cathode or the anode. The electrolyte can serve as a reaction propellant or even as an integral part of the reaction. This combination of reactions is referred to as *redox*. [Table 8](#) provides redox reaction potentials for eight elements.

Lithium and fluoride generate the highest potential during oxidation and reduction, respectively [7]. A significant advantage of lithium-ion batteries is their efficiency in charge retention and energy supply. The internal resistance of lithium-ion cells is comparatively low, which means they do not lose a considerable amount of energy as heat (I^2R loss) [8]. In general, the internal resistance of a cell is modeled as a resistor in series with an ideal voltage source. Maximum efficiency occurs with a low internal series resistance and a large load resistance. Maximum power can be extracted from a cell when load resistance is equal to the cell's internal resistance. Under this condition half the total power is expended as heat, while the other half is available for use. The availability of high power output is a useful property for lithium-ion cells, especially when instantaneous power is required. Consider the example of a race car looking to set a new

Battery Technologies. Table 8 Redox potential [7]

Electrode reaction	Potential (V)	Electrode reaction	Potential (V)
$\text{Li}^+ + e \leftrightarrow \text{Li}$	−3.01	$\text{Cu}^{2+} + 2e \leftrightarrow \text{Cu}$	0.34
$\text{Na}^+ + e \leftrightarrow \text{Na}$	−2.71	$\text{Ag}^+ + e \leftrightarrow \text{Ag}$	0.80
$\text{Ni}^{2+} + 2e \leftrightarrow \text{Ni}$	−0.23	$\text{Cl}_2 + 2e \leftrightarrow 2\text{Cl}^-$	1.36
$\text{Pb}^{2+} + 2e \leftrightarrow \text{Pb}$	−0.13	$\text{F}_2 + 2e \leftrightarrow 2\text{F}^-$	2.87

quarter-mile speed record. This car would need high instantaneous power without regard to cell degradation due to overheating.

Operation

Numerous lithium-based alloys are available for use as anode. Lithium polymers are considered commercially safe, while metallic lithium is still at the developmental stage [17]. Charge flow for any of the combinations in [Fig. 19](#) is typically the same, as shown in [Fig. 20](#).

A common electrolyte is lithium hexafluorophosphate (LiPF_6). It was chosen for its high redox potential. Ehsani et al. [17] mentions that LiPF_6 is unstable under high heat and moisture. Hydrofluoric acid (HF) is produced as a by-product to the electrolyte's reaction with water. For this reason, there was significant opposition to its use in the early 1990s. Since then however, it has been revealed that a small amount of HF increases life cycle, because of the formation of a strong passive layer on the cathode.

The addition of HF prevents formation of lithium dendrite. (Most metals are combined with alloys for dexterity and strength. Due to the presence of alloys, the metal tends to exist in a nonuniform, snowflake-like distribution called *dendrite*.) LiPF_6 is also easily soluble in the solvent, making it a good solid interface on the surface of anode materials. Lithium-ion is considered to be the current generation technology for EV batteries, in part because of its high energy density. Also, lithium has the highest redox reaction potential of any metal. It is also necessary to consider the fact that key elements of lithium-ion batteries are facing exhaustion. Cobalt metal, used for cathode, has been in shortage for quite some time [17]. Most metals are combined with alloys for dexterity and strength. Due to the presence of alloys, the metal tends to exist in a, nonuniform, snowflake-like distribution called dendrite [17].

Battery Technologies. Figure 19

Numerous chemical combinations for lithium-ion batteries

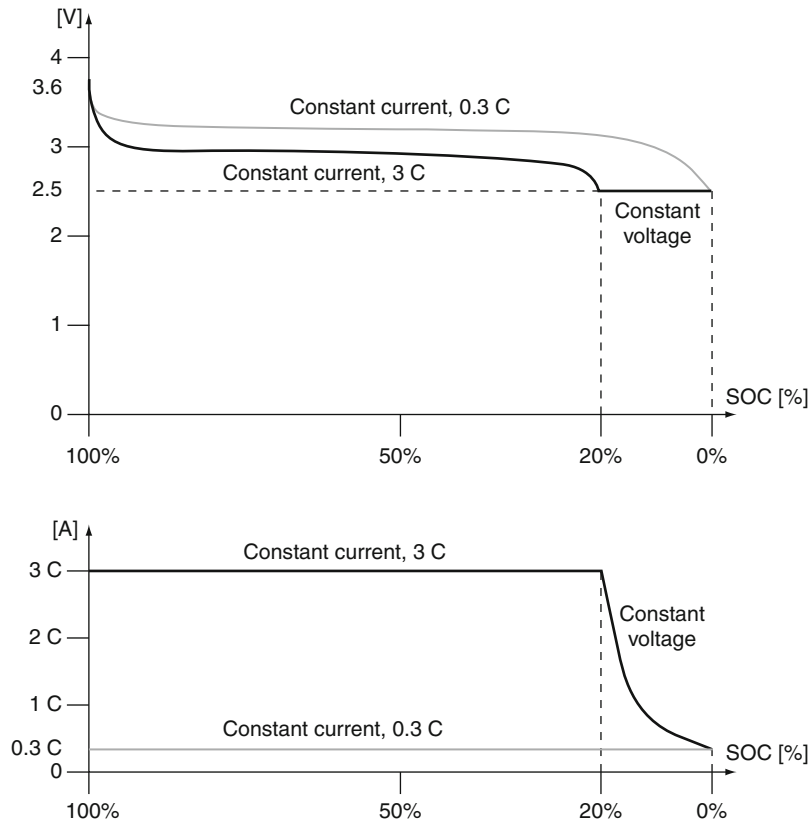

Battery Technologies. Figure 20

Charge flow for lithium-ion batteries [17]

Efficiency

Lithium-ion batteries are practically 100% charge efficient, according to Brodd et al. [5]. In essence, all the charge lost during discharging is recovered during charging. Note that there is a net loss in energy during each complete charging/discharging cycle. This is because the cell voltage is lower during discharging as compared to the charging cycle. Figure 21 provides discharge curves for voltage and current of a lithium-ion cell. Note that the voltage continues to drop during discharge before stagnating at a constant level toward the end of charge availability. This constant voltage can be attained by discharging at a lower current, as shown in the current curve of Fig. 21. As the current drops to zero, the total charge from the cell adds up to the same value regardless of the rate of discharge (whether the discharge was at a low current or at a high current) [5].

Battery Technologies. Figure 21

Voltage and current during discharge [18]

Applications that require constant current will be unable to extract the last bit of energy out the battery. Other applications, such as for EVs, have more flexibility. Some of today's EVs can operate at lower torque, which implies lower current, to allow the driver to reach a safe location before running out of battery power. Such applications can use the entire charge contained in a battery.

Although not obvious, both the graphs in Fig. 21 are related. As a cell ages, it appears to gradually lose capacity. Davide [18] explains that this capacity is actually unused, but not lost. Internal resistance of a cell increases with age, therefore the cell gets undercharged and under-discharged along the process. This issue can be resolved by allowed fixed cutoff voltages to vary internally. Due to fixed cutoff voltages, the cell charges/discharges less and less each time due to increasing internal resistance, resulting in an apparent loss of capacity. By raising the upper cutoff voltage

during charge and lowering the lower cutoff voltage during discharge, we can recover some of this lost capacity. A battery management system that is able to measure a cell's internal resistance and compensate its cutoff voltage accordingly can make better use of the cell's capacity [18].

Reliability

To minimize operation and maintenance (O&M) costs for the customer, it is essential for a battery manufacturer to conduct rigorous stress tests on their battery systems. A common test adapted by manufacturers in the USA is known as the dynamic stress test (DST), developed by the United States Advanced Battery Consortium (USABC). Figure 22 shows an example of the battery charging and discharging power profiles that must be successfully followed to acquire DST conformation. The test can be performed at various temperatures to determine ideal operating conditions. The test

Battery Technologies. Figure 22

Dynamic stress test by USABC [19]

Battery Technologies. Figure 23

DST results for Saft's lithium-ion battery [20]

is designed to gauge battery performance characteristics such as partial discharge and hold, sustained climb, thermal performance, and fast charge response. One such battery was tested by the Electric Power Research Institute (EPRI). Figure 23 shows DST results of that battery, specifically energy storage capacity versus number of DST test cycles at 80% depth of discharge. As

shown, a 12.5% drop in capacity is attained after 3,000 cycles. This is in contrast to a 37% drop in capacity for NiMH batteries subject to a similar test [20]. Longer life expectancy combined with larger power density make lithium-ion batteries an ideal candidate for EVs.

Twenty watt-hours of energy storage capacity is lost after 3,000 charge–discharge cycles, as seen in Fig. 23.

Thermal Runaway

Thermal runaway (TR) is defined as a phenomenon where an increase in temperature creates conditions for further increases in temperature. Viable conditions for TR exist when a battery is producing more heat than it can dissipate. Thermal runaway can lead to leaks, venting of gas, and possibly a fire. According to Saft, temperature in a cell must be kept below 145°C to prevent conditions for TR from arising.

As battery temperature typically increases during operation, resistance of the ion-transferring electrolyte decreases. This leads to an increase in the current passing through the battery, raising the temperature of the battery even further. If the electrolyte becomes too hot, its resistance will become negligible and allow enough current to flow for chemical compounds on the cathode and anode to breakdown and short circuit.

Excessive ambient temperatures are another cause of TR, according to Saft. Computers, cell phones, and other portable devices are often subject to prolonged exposure to direct sunlight. Additionally, portable electronics could be operated in constricted spaces, with insufficient room for heat dissipation. High ambient temperatures can also harbor conditions for TR.

EPRI identifies overcharging as yet another source for TR [20]. Overcharging can lead to build up of lithium deposits that can penetrate the film separating

the anode and the cathode, leading to a short circuit. All lithium-based batteries are equipped with protective circuitry to avoid overcharging. Failure of protective circuitry can lead to build up of lithium-ions on the graphite anode, forming lithium dendrite. (Most metals are combined with alloys for dexterity and strength. Due to the presence of alloys, the metal tends to exist in a nonuniform, snowflake-like distribution called *dendrite*.) With increasing formation of this dendrite, useful anode surface area diminishes, leading to reduced battery capacity. If charging continues even further, the dendrite will penetrate the separator and react with the cathode, creating a short circuit. Metallic lithium is still at the developmental stage because it is prone to dendrite formation. Figure 24 depicts EPRI's projection of effects of storage temperature on battery life.

Irrespective of the cause, TR is a dangerous prospect. Potential large-scale use will require development of adequate prevention of conditions leading to TR [20]. USABC and EPRI have proposed various solutions, albeit with negative impacts on power density and capacity.

Capacity Fading

Capacity fading (CF) refers to reduction in battery capacity after repeated charge or discharge cycles.

Battery Technologies. Figure 24

Projected calendar life as a function of storage temperature [20]

Yunjian et al. [21] uses a lithium-ion battery, with lithium manganese oxide (LiMn_2O_4) as cathode and graphite as anode to study capacity fading characteristics. Lithium hexafluorophosphate (LiPF_6) is present as an electrolytic salt. The battery was charged to 4.2 V and then stored for a period of 96 h at 55°C. A notable reaction was the formulation of hydrofluoric acid (HF) and a consequent dissolution of manganese (Mn). The following reactions were noted:

Mn^{2+} enters the electrolyte and manganese dioxide (MnO_2) is deposited on the cathode. A reported 8 mAh/g of capacity was lost on the first day. Only 2 mAh/g of capacity was lost during each of following 3 days. MnO_2 formation on the cathode protected it from engaging in further dissolution of manganese (Mn), which explains the dwindling in CF. Charge retention of the battery was found to be 83.3%, 85.8%, 86.9%, and 88.6% for those 4 days.

Elevated temperatures can accelerate the rate at which CF occurs, as evident from work done by Xia et al. [22]. When operated above 65°C, the number of operational cycles is well below the EV requirement of 1,000–1,500. Degradation of electrode materials has been found to be the main reason for CF at high temperatures [22].

Cost

Lithium-based batteries are subject to aging even if not being used. Also, lithium batteries are dependent on protective circuits to maintain safe levels of voltage and current. These factors propagate into a 40% (average) higher manufacturing cost for lithium-based batteries compared to NiMH [20]. Figure 25 provides a breakdown of costs to manufacture an EV lithium-ion battery.

Several automotive manufacturers have announced plans to incorporate lithium-based batteries for use in HEVs, although NiMH batteries currently predominate. Lithium-ion batteries store more than twice as much energy per kilogram (250–400 Wh/kg) compared to the next-best battery technology, NiMH.

Battery Technologies. Figure 25

Component costs as percentage for Saft's EV lithium-ion battery [18]

After having purchased their EV, customers are now responsible for operating costs for as long as they own the vehicle. Operating costs can vary based on battery capacity, efficiency, environmental conditions, and usage. Nevertheless, once gas savings balance out the cost of the EV, long-term savings in operating costs become apparent. A lab experiment conducted by EPRI in 2010 [23] employed various EV types, each with a lithium-ion battery system. Operating costs (loosely termed “fueling costs”) are shown in Fig. 26. Here, the following EV types were used: Fuel Cell Vehicle (FCV), Plug-in Fuel Cell Vehicle (PFCV), Range Extender Fuel Cell Vehicle (FCV), Battery Electric Vehicle (BEV), and Plug-in Hybrid Electric Vehicle (PHEV). A “20” (or “40”) in the name indicates 20 (or 40) miles on a full charge.

In the near term, FCVs are more expensive due to the cost of hydrogen. The FCV fitted with a range extender module uses considerably lesser hydrogen, as consistent with the lower near term operating cost. As expected, predominant battery use in EVs results in lower near term costs. In the long term, the difference in cost of hydrogen versus electricity became smaller, as apparent in the near identical long-term costs for all vehicle types.

To make lithium-ion batteries practical for mass-produced electric-drive vehicles, new technologies

Battery Technologies. Figure 26
Operational costs per mile for various Li-ion EV configurations [23]

Battery Technologies. Figure 27
Cost breakdown for complete battery pack used for typical PHEV40

must increase the energy the batteries store and the speed with which they can discharge it. They must also lengthen cycle life to 15 years or 241,000 km (150,000 miles) – the average life of a vehicle [24].

Perhaps it would be appropriate to compare lithium ion to other chemistries in terms of cost of a battery pack for EVs. Figure 27 provides such

a comparison for a PHEV-40, as per 2010 cost estimates made by EPRI’s Duvall et al. [23] and the Electric Auto Association.

Notably, Pb-A and NiMH (best case) appear to carry the lowest and highest overall costs respectively. It is important to mention that a typical EV lead acid battery pack only has a life of approximately

14–16 months (assuming the vehicle is driven 20–40 miles daily). On the other hand, the NiMH pack has a life span of roughly 5.5 years.

Metal–Air Batteries

Metal–air batteries get their name from their reactants which undergo electrochemical reactions to release energy. They are one of the most compact and potentially the least expensive batteries available. They are also environmentally friendly. However, their main disadvantage so far has been that electrical recharging of these batteries is very difficult and inefficient. Although many manufacturers offer units that can be refueled, where the consumed metal is mechanically replaced and processed separately, there still have not been many developers who offer rechargeable batteries. Rechargeable metal air batteries that are under production have a life of only a few hundred cycles and an efficiency of about 50% [1, 6].

Current research in lithium–air batteries have shown that they can provide an energy density of 1,700 Wh/kg, which is more than the energy density of any other battery technology present today and is comparable to the practical energy density of gasoline [6] (Fig. 28).

Air electrodes and metal–air battery technologies have already been used in fuel cell systems. Earlier, zinc was the predominant metal used in metal–air batteries. Recently, lithium instead of zinc as the metal has started being used which has increased the energy output eightfold. As seen in the figure above, the lithium–air battery's porous carbon cathode (gray) is flooded

with the electrolyte (blue). The Li^+ ions (small dots) react with oxygen molecules (pairs of dots) at catalyst sites (yellow) to form lithium oxides (orange). The oxygen electrode proceeding in tandem with lithium according to the reaction $2\text{Li} + \text{O}_2 \rightarrow \text{Li}_2\text{O}_2$ can deliver a capacity of 1,200 mAh/g. The first lithium–air cell was successfully assembled and discharged in 1996, but attractive rechargeability was demonstrated only recently [3].

It could be argued that such a system unites within the same device the two most prominent failures of battery and fuel-cell technologies, namely, the inability to master lithium and oxygen electrodes. These perceived issues have prevented the practical use of lithium–air batteries. Improving energy storage and preventing Li_2O_2 from clogging the electrode require a better understanding of the reaction mechanism of the oxygen electrode. Engineering and chemical advances are also required to prevent the ingress of either CO_2 or H_2O , which could react with either Li_2O_2 or lithium metal [3].

Zinc Bromine Battery

The zinc bromine battery is based on the chemical reactions between two commonly available materials, zinc and bromine. This battery was developed by Exxon in the early 1970s. It is a hybrid flow battery system since zinc is deposited on the negative electrode during the charge cycle. Unlike conventional flow batteries, the energy storage capacity of the zinc–bromine hybrid is constrained by the amount of surface area available for deposition [4, 9].

Battery Technologies. Figure 28

Li–air battery [6]

One of the main advantages of zinc–bromine batteries is that it can be fully discharged without any damage to the battery and has a life of at least 1,500 charge/discharge cycles. This battery is ideally suited in applications that require deep cycle and long cycle life energy storage. These batteries are made with low-cost, recyclable plastics and manufactured with techniques suitable for mass production and at low production costs [4].

As seen in the figure below, the battery consists of a zinc negative electrode and a bromine positive electrode separated by a microporous separator. An aqueous solution of zinc/bromide is circulated through the two compartments of the cell from two separate reservoirs. The electrolyte stream in contact with the positive electrode contains bromine which is maintained at the desired concentration by equilibrating with a bromine storage medium. The bromine storage medium is immiscible with an aqueous solution containing zinc bromide. All battery components are made from a bromine inert plastic [4] (Fig. 29).

During discharge, zinc is converted to zinc ion with the release of two electrons and bromine is converted to bromide, the zinc ion and bromine combine to form zinc bromide. The chemical process used to generate the electric current increases the zinc-ion and bromide-ion concentration in both electrolyte tanks. During charge, metallic zinc is deposited as a thin film on one

side of the plastic electrode. Meanwhile, bromine is evolved as a dilute solution on the other side of the membrane, reacting with other compounds in solution (organic amines) to form viscous, dense bromine-adduct oil that sinks to the bottom of the tank. The bromine oil is allowed to mix with the rest of the electrolyte during discharge. The net efficiency of this battery is about 75% [9].

The zinc–bromine battery uses electrodes that do not take part in the reactions but merely serve as substrates for the reactions. Therefore, there is no loss of performance, as in most rechargeable batteries, from repeated cycling causing electrode material deterioration. When the zinc–bromine battery is completely discharged all the metal zinc plated on the negative electrodes is dissolved in the electrolyte and again produced the next time the battery is charged. In the fully discharged state the zinc/bromine battery can be left indefinitely [4].

The zinc–bromine battery has an energy density of 75–85 Wh/kg. The power characteristics of the battery can be modified for selected applications, making them extremely useful for multipurpose energy storage [4].

Supercapacitors

In the field of energy storage, two parameters are fundamental for storage devices: the energy density and

Battery Technologies. Figure 29
ZnBr battery [4]

the power charging and discharging rates. The first parameter defines the amount of energy that can be stored in a given volume. The lower the maximum charging and discharging rates, the more time that is required for loading and unloading the required amount of energy into the storage device. The ideal storage device should have both a high energy density together with high power charging and discharging rates. This is unfortunately not the case and compromises have to be made. Current battery technologies have relatively high energy densities but relatively poor power densities. Supercapacitors are a compromise between batteries and conventional capacitors. Their main characteristic is that they possess both a relatively high energy density and power density [25].

Integrating with an Onboard Energy Source for an EV

The integration of the onboard energy source for an electrically propelled vehicle with a supercapacitor bank (SB) as a peak power unit can lead to substantial benefits in terms of EV performances, battery life, and energy economy. An SB made up of single cells connected in series and in parallel, featuring appropriate parameters of energy density, power density, with high charging–discharging efficiency and affordable cost can be beneficial as a suitable device to support the energy source of an electric vehicle, thus providing optimized energy management [26].

The potential benefits of an integrated system SB-electrochemical energy source are the following:

- To improve the vehicle efficiency and energy economy over variable power driving conditions
- To assure high performance and good vehicle behavioral response independently from the status of the energy source (including age)
- To improve the endurance of the energy source to the extent of its dependence on the high rate power demand
- To extend the vehicle's range at full performance as a consequence of the combined effect of load leveling of the onboard energy source and of better efficiency of energy recovery

Second to the range of the EV, high acceleration performance is a highly desired feature to achieve

integration with the majority of today's vehicles. The integration of an SB with a battery allows a system design optimized according to driving requirements, by making the specific power and specific energy parameters of the energy source independent of each other. As a consequence of this consideration, it will be possible to design the storage battery with respect to energy storage capability and life requirement without taking into account the power requirement [26].

Difference Between Capacitors and Supercapacitors

A supercapacitor differs from a conventional capacitor both in the physical phenomena and the materials from which it is made. In today's supercapacitors, the dielectric is an electrolyte interposed between two electrodes. When a voltage is applied, a double layer of charges is formed at the interface between the electrodes and the electrolyte. In the case of supercapacitors, the distance between the charges corresponds to the thickness of the double layer, that is, only a fraction of a nanometer. This accounts for the difference in terms of capacitance per square centimeter between a conventional capacitor in the (order of magnitude nF/cm^2) and a supercapacitor (order of magnitude $50,000 \text{ nF}/\text{cm}^2$) [26].

The way to increase the energy stored in a conventional capacitor is to operate at high voltages (up to 3,000 V) consistent with the dielectric breakdown voltage. In today's supercapacitors, the voltage to be applied must be limited by either the solvent or the organic electrolyte decomposition voltage (1.23 V and 3.5 V, respectively). In this case, the only way to increase the stored energy is to raise the capacitance value by adopting electrode materials with very high specific area. In particular, active carbon may reach, through suitable chemical processes, a specific area of $103 \text{ m}^2/\text{g}$, and a specific capacitance of 102 F/g . In addition, it is possible to reach very low values of the internal resistance that allows the device to provide high output power.

So far, only supercapacitors operating on the basis of charge separation phenomena due to the application of an external voltage between the electrodes have been considered. There is another type of supercapacitor, called pseudocapacitor, in which reduction and oxidation reactions occur during charge and discharge phases. The electrodes are made of metallic oxides

Battery Technologies. Table 9 Characteristics of supercapacitors based on the electrode and electrolyte material [26]

Electrode material	Carbon	Carbon	Metallic oxides
Electrolyte	Aqueous electrolyte	Organic electrolyte	Aqueous electrolyte
Maximum voltage (V)	1	3	1
Specific power (kW/kg)	0.8–2.6	1.5–5	0.5
Specific energy (Wh/kg)	0.2–1.3	3–6	1

(typically ruthenium or iridium) and electrolytes are liquid. The characteristics of supercapacitors are summarized as in Table 9 [26, 27].

Working Principle of a Supercapacitor

Supercapacitors are electrochemical double layer capacitors (EDLC). Their technology is similar to that of batteries, but the main difference is that they involve only electrostatic phenomenon (non-faradic). This is the first difference between batteries and supercapacitors. Their power density is higher because there are no chemical reactions during charging and discharging. Also, for this reason, charge storage in EDLCs is highly reversible, which allows them to achieve very high cycling stabilities. EDLCs generally operate with stable performance characteristics for many charge–discharge cycles, sometimes as many as 10^6 cycles. On the other hand, electrochemical batteries are generally limited to only about 10^3 cycles. In double-layer capacitors, the energy is stored by charge transfer at the boundary between electrode and electrolyte. The amount of stored energy is a function of the available electrode surface, the size of the ions, and the level of the electrolyte decomposition voltage [25].

Supercapacitors contain two electrodes, a separator and an electrolyte, as shown in Fig. 30. The two electrodes provide a high surface area, defining the energy density of the component. On the electrodes, current collectors with a high conducting part assure the interface between the electrodes and the connections of the supercapacitor. The two electrodes are separated by

Battery Technologies. Figure 30
Principle of supercapacitors [25]

a membrane, which allows the mobility of the charged ions and forbids electronic contact. The electrolyte supplies and conducts the ions from one electrode to the other. As the dissociation voltage of the electrolytes used is less than 3 V, this limits the maximum voltage that can be reached by the supercapacitor. Another disadvantage is lower ionic conductivity, which reduces the power capability [25].

The performance of an electrochemical double layer supercapacitor (EDLC) can be adjusted by changing the nature of its electrolyte. As mentioned earlier, an EDLC can utilize either an aqueous or organic electrolyte. Aqueous electrolytes generally have lower equivalent series resistance (ESR) compared to organic electrolytes. However, aqueous electrolytes also have lower breakdown voltages. Therefore, in choosing between an aqueous or organic electrolyte, one must consider the trade-offs between capacitance, ESR, and voltage. Because of these trade-offs, the choice of electrolyte often depends on the intended application of the supercapacitor [27].

While the nature of the electrolyte is of great importance in supercapacitor design, the subclasses of EDLCs are distinguished primarily by the form of carbon they use as an electrode material. Carbon electrode

materials generally have higher surface area, lower cost, and more established fabrication techniques than other materials such as conducting polymers and metal oxides.

Electrode Materials Used in EDLC

Activated Carbon Activated carbon is the most commonly used electrode material in EDLCs. It is less expensive and possesses a higher surface area than other carbon-based materials. Activated carbons utilize a complex porous structure composed of different sized micropores (<200 nm wide), mesopores (200–5,000 nm) and macropores (>5,000 nm) to achieve high surface areas. Although capacitance is directly proportional to surface area, evidence suggests that, for activated carbons, not all of the high surface area contributes to the capacitance of the device. This discrepancy is believed to be caused by electrolyte ions that are too large to diffuse into smaller micropores, thus preventing some pores from contributing to charge storage [27]. Research also suggests an empirical relationship between the distribution of pore sizes, energy density, and power density of the device. Larger pore sizes correlate with higher power densities and smaller pore sizes correlate with higher energy densities. As a result, the pore size distribution of activated carbon electrodes is a major area of research in EDLC design. In particular, research has been focused on determining the optimal pore size for a given ion size and upon improving the methods used to control the pore size distribution during fabrication [27].

Carbon Aerogels There is an increasing interest in using carbon aerogels as an electrode material for EDLCs. Carbon aerogels are formed from a continuous network of conductive carbon nanoparticles with interspersed mesopores. Due to their continuous structure and their ability to bond chemically to the current collector, carbon aerogels do not require the application of an additional adhesive binding agent. As a result of this, carbon aerogels have lower ESR than activated carbons. (The internal components of the capacitor (current collectors, electrodes, and electrolyte) contribute to a resistance, which is measured in aggregate by a quantity known as the equivalent series resistance (ESR). The voltage during

discharge is determined by this resistance.) The reduced ESR yields higher power and this is the primary area of interest in supercapacitor research involving carbon aerogels [27].

Carbon Nanotubes Electrodes made from this material are grown as an entangled mat of carbon nanotubes with an open and accessible network of mesopores. Unlike other carbon-based electrodes, the mesopores in carbon nanotube electrodes are interconnected, allowing a continuous charge distribution that uses almost all of the available surface area. Thus, the surface area is utilized more efficiently to achieve capacitance comparable to those in activated-carbon-based supercapacitors, even though carbon nanotube electrodes have a smaller surface area compared to activated carbon electrodes [27]. As the electrolyte ions can easily diffuse into the mesoporous network, carbon nanotube electrodes also have a lower ESR than activated carbon. In addition, several fabrication techniques have been developed to reduce the ESR even further. Carbon nanotubes can be grown directly onto the current collectors, subjected to heat-treatment or cast into colloidal suspension thin films [27]. The efficiency of the entangled mat structure allows higher energy densities [27].

Pseudocapacitors

In contrast to conventional EDLCs, which store charge electrostatically, pseudocapacitors store charge faradically through the transfer of charge between electrode and electrolyte. This is accomplished through electrosorption, reduction–oxidation reactions, and intercalation processes. These faradic processes may allow pseudocapacitors to achieve greater capacitances and energy densities than EDLCs. There are two electrode materials that are used to store charge in pseudocapacitors, conducting polymers and metal oxides [27].

Electrode Materials Used in Pseudocapacitors

Conducting Polymers Conducting polymers have a relatively high capacitance and conductivity and a relatively low ESR and cost compared to carbon-based electrode materials [27]. In particular, the *n/p*-type polymer configuration, with one negatively

charged (*n*-doped) and one positively charged (*p*-doped) conducting polymer electrode, has the greatest potential energy and power densities. However, a lack of efficient *n*-doped conducting polymer materials has prevented these pseudocapacitors from reaching their potential. Additionally, it is believed that the mechanical stress on conducting polymers during reduction–oxidation reactions limits the stability of these pseudocapacitors through many charge–discharge cycles. This reduced cycling stability has hindered the development of conducting polymer pseudocapacitors [27].

Metal Oxides Metal oxides like ruthenium oxide have high conductivity, which makes them a good electrode material for supercapacitors [27]. The capacitance of ruthenium oxide is achieved through the insertion and removal of protons into its amorphous structure. In its hydrous form, the capacitance exceeds that of carbon-based and conducting polymer materials. Furthermore, the ESR of hydrous ruthenium oxide is lower than that of other electrode materials. As a result, ruthenium oxide supercapacitors may be able to achieve higher energy and power densities than similar carbon electrode supercapacitors. However, despite this potential, the success of ruthenium oxide has been limited by its prohibitive cost. Thus, a major area of research is the development of fabrication methods and composite materials to reduce the cost of ruthenium oxide, without reducing the performance [27].

Composite Electrode Capacitors Composite electrodes integrate carbon-based materials with either conducting polymer or metal oxide materials and incorporate both physical and chemical charge storage mechanisms together in a single electrode. The carbon-based materials facilitate a capacitive double layer of charge and also provide a high-surface-area backbone that increases the contact between the deposited pseudocapacitive materials and electrolyte. The pseudocapacitive materials further increase the capacitance of the composite electrode through faradic reactions [27]. Composite electrodes constructed from carbon nanotubes and polypyrrole, a conducting polymer, have been particularly successful. This electrode is able to achieve higher capacitances than either a pure

carbon nanotube or pure polypyrrole polymer-based electrode [27]. This is attributed to the accessibility of the entangled mat structure, which allows a uniform coating of polypyrrole and a three-dimensional distribution of charge. Moreover, the structural integrity of the entangled mat limits the mechanical stress caused by the insertion and removal of ions in the deposited polypyrrole. Therefore, unlike conducting polymers, these composites have been able to achieve a cycling stability comparable to that of EDLCs having carbon-based electrodes [27].

Model for Supercapacitors

A conventional model describing the supercapacitor modeled as an equivalent electrical circuit is useful for developments of applications where supercapacitors can be used. Figure 31, below, shows such a model.

The first parameter is the capacitance of the component. It defines the capacitive behavior of the supercapacitor and the energy that can be stored. This capacitance is not constant. It is dependent on the voltage across and is the reason why the capacitance of the supercapacitor is modeled as a constant capacitor C_o , with a parallel capacitor C_v , which has a linear dependence on the voltage V [25].

$$C = C_o + C_v, \text{ where } C_v = K \bullet V \quad (3)$$

This defines the capacitance C of the component.

Following this definition, the current capacitance can be derived from (3).

$$Q = CV$$

$$I_c = dQ/dt$$

Therefore,

$$I_c = (C_o + 2K \bullet V)dV/dt \quad (4)$$

$$\text{Current capacitance } C_i = C_o + 2K \bullet V$$

Similarly, energy capacitance can also be defined.

$$\text{Power (P)} = I_c \bullet V = (C_o + K \bullet V^2)dV/dt \quad (5)$$

$$\text{Energy (W}_w) = 1/2(C_o + 4/3(K \bullet V))V^2 \quad (6)$$

$$\text{Energy capacitance (C}_w) = C_o + 4/3(K \bullet V) \quad (7)$$

The amount of energy that can be stored into a supercapacitor can be expressed as a function of the

Battery Technologies. Figure 31

Equivalent circuit model for supercapacitors [25]

Battery Technologies. Table 10 Energy capability versus the capacitance [25]

Capacitance	$C = 1,800 \text{ F}$	$W = 5,625 \text{ J}$	
Current capacitance	$C_i = 2,100 \text{ F}$	$W_i = 6,562 \text{ J}$	+16.65% increase
Energy capacitance	$C_w = 1,850 \text{ F}$	$W_w = 5,781 \text{ J}$	+2.77% increase

capacitance that is considered. This is summarized for a 1,800 F/2.5 V supercapacitor, where measurements for $C = 1,800 \text{ F}$ and $K = 150 \text{ F/V}$ in Table 10.

The current capacitance C_i shows that it is possible to store 16.55% more energy than expected considering only the constant capacitance given by the manufacturer. Another consequence of this voltage-dependent capacitance is that the voltage will not increase linearly during the charge with a constant current. Two other parameters are conventional for a supercapacitor model. The first one is the series resistor R_s that induces voltage drops during charge and discharge. Its value influences the energy efficiency of the component and its power density. The second conventional parameter is the leakage resistor R_l that induces load losses when

the component is in a standby mode. However, this resistor is not the only parameter that influences the voltage variation across a supercapacitor between a charge and discharge operation. This is illustrated in Fig. 32 [25].

The upper curve shows the typical voltage variation V_c across a 800 F/2.5 V supercapacitor during the end of its charge with a constant current. Once the charge is ended, the voltage decreases rapidly. This could be due to the leakage resistor but this is not strictly the case if the model in Fig. 31 is considered again. It makes n parallel RC circuits appear. This is illustrated in the lower part of Fig. 32 where the relaxation phenomena are presented as the charge of RC circuits with different constant times. The result is a decrease of the main voltage, not due to a dissipative component, but due to a homogenous arrangement of the loads and ions on the electrodes and in the electrolyte. Once all the voltages across all the equivalent capacitors are equal, then relaxation phenomena are supposed to be ended. The decrease of the main voltage is then linked to a leakage current. An ideal supercapacitor model should propose an infinite number of RC branches. For practical reasons linked to measurement, most of the models identify only two or three of these equivalent subcircuits [25].

Battery Technologies. Figure 32

Relaxation phenomena [25]

Sizing Method of a Supercapacitive Tank

For a supercapacitor, the total amount of energy W_M that can be stored is expressed as a conventional capacitor:

$$W_M = \frac{1}{2}(C \bullet V_M^2) \quad (8)$$

where C is the capacitance of the component and V_M is the maximum voltage. The voltage across the component has to be decreased from its maximum allowed value to 0 V for the use of the total amount of stored energy. This is not possible because the current provided by the supercapacitor should be infinite. For this reason, the minimum voltage when discharging the component has to be limited and all the energy stored in the component is not used [25]. It is then necessary to define the parameter d , which is the ratio between the minimum allowed voltage V_m for the discharging,

and the maximum voltage V_M that defines a full charging of the component. d is expressed in percent and is called the discharge voltage ratio:

$$d = (V_m/V_M) \bullet 100 \quad (9)$$

Under this condition, the usable energy W_v that a supercapacitor can provide is given by the equation:

$$W_v = W_M(1 - (d/100)^2)^2 \quad (10)$$

If $d = 50\%$, the voltage is half of the maximum voltage at the end of the discharge, then the usable energy W_v will be 75% of the total stored energy W_M . For a given usable energy, the last two equations can be combined to identify the number of supercapacitors in the supercapacitor bank.

$$N_s = 2W_v/CV_M^2(1 - (d/100)^2) \quad (11)$$

Battery Technologies. Table 11 Sizing of a supercapacitor tank

N_s	d (%)	Volume (m^3)	Weight (kg)	E (kWh)
4,872	50	1.46	1,943	7.6
5,709	60	1.71	2,283	8.92
7,164	70	2.15	2,865	11.2

Let us take an example where the supercapacitor is 1,800 F/2.5 V and the usable energy $W_u = 0.55$ MJ = 5.7 kWh. The corresponding sizing of a supercapacitive tank is given for three different values of d according to (10) and this supercapacitor in Table 11 [25].

$$W_v = 0.55 \text{ MJ}, C = 1800, F_{U_M} = 2.5, V_{I_M} = 200 \text{ A}$$

The best choice should define a SB with $d = 50\%$ because of the reduced number of supercapacitors and because the usable energy W_v is 75% of the maximum stored energy W_M . On another hand, the choice of $N_s = 7,164$ ($d = 70\%$) leads to a strong oversizing of the SB where the usable energy W_v is only 51% of the maximum stored energy. This offers an interesting versatility in the management of the energy that has to be provided. If that tank and its associated power converters are designed for $d = 70\%$, it will be possible to vary the voltage more than that limit in case of stronger random power constraints [25].

Energy Efficiency and Power Availability

One of the main parameters of a supercapacitor is its series resistance. Independent of voltage falling during charge and discharge, internal losses are due to this element. Even if manufacturers succeed in reducing the value of the series resistor, its value induces an energy efficiency lower than unity with the consequence of a reduction of the power availability [25].

The energy efficiency of supercapacitors is taken into consideration while sizing a supercapacitive tank because the way supercapacitors are charged and discharged influence their performance. One of the only ways to control the charging/discharging process is to develop

Battery Technologies. Figure 33
Interfaces for supercapacitors [25]

power electronics interfaces in order to control the current for loading/unloading the supercapacitors [25]. This is illustrated in Fig. 33. The charge of supercapacitors is realized with a constant current, as shown in Fig. 34, where supercapacitors are loaded from a dc voltage source. The charging/discharging current is adjusted to maintain the product of $v_c I$ constant. The value of the charging/discharging current or power will define the energy efficiency of the supercapacitive tank together with the value of the equivalent series resistor. This is illustrated in Fig. 35 where the voltage discharge ratio d is 50%. In this case, 75% of the total used energy is loaded and unloaded for a 2,600 F/2.5 V/0.7 mΩ supercapacitor. The energy efficiency is presented versus the time, the current, or the power needed for loading/unloading the component [25].

The time for loading energy is chosen to be 10 s. Its energy efficiency is expected to be over 90%. This means a charging current limited to 320 A or a charging constant power limited to 700 W. The same can be applied to the current or the power during discharge. The constant power has to be kept lower than 420 W to obtain more than 90% energy efficiency. This has a consequence on the power density of the component which is 4,300 W/kg. Taking into account the energy efficiency, the power density will only be 806 W/kg if the energy efficiency is to be kept higher than 90%. This leads to an increased number of supercapacitors for the design of a storage tank. Therefore, the energy efficiency and the power availability both have to be taken into account for the design of a supercapacitor storage bank. The final parameter to be taken into account is the efficiency of the power converter needed for interfacing the supercapacitors with their load [25].

Battery Technologies. Figure 34
Charging characteristics [25]

Power Train System Architecture

Architecture conceived with the electronic interface between the SB and the traction battery are shown in Fig. 36 below.

The main characteristics of this architecture are:

- The DC-to-DC converter has to be dimensioned for the maximum power flow into and out of the SB [26].
- The SB voltage may be kept always lower than the minimum traction battery voltage. As a consequence, a simpler DC-to-DC converter design may be obtained. The DC-to-DC converter may operate only in step-up mode during the traction phase and only in step-down mode during the braking phase [26].
- A lower operating voltage implies a lower number of cells connected in series and a reduced complexity of the electronic module of the SB [26].

- The possibility to add an auxiliary generator (auxiliary power unit) configuration without modifying the existing structure [26].

Future Developments in Supercapacitors

Currently, there is work in progress on the development of supercapacitors using solid dielectrics.

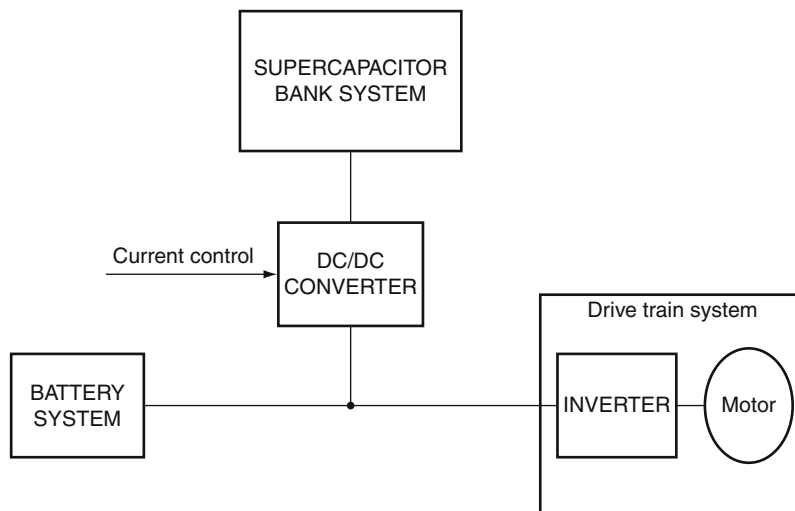

The energy density stored in a capacitor is given by:

$$W = \frac{1}{2} \epsilon_o \epsilon_r E^2$$

ϵ_o is the dielectric constant of free space, ϵ_r is the relative dielectric constant, and E is the electric field strength. Relative dielectric constants of 200,000 have been measured for 500 nm particles of BaTiO₃ coated with 5 nm of SiO₂ [28]. If these particles can be fabricated into supercapacitors with breakdown electric field strengths of the order of the breakdown strength of SiO₂, around 6×10^6 V/cm, then energy densities of the order of

Battery Technologies. Table 12 Recommendations for future work

Action	Short term	2011–2013	2012–2016	2015–2020
Develop value propositions for storage to enable more renewable integration	Conduct assessment of utility and private renewable integration	Simulation and cost-benefit analysis of renewable plants and private systems	Large-scale demonstrations	Value and risk of renewable integration verified by the utility and understood by the end user
Development and enforcement of regulations	Develop target for development of regulations to address issues and risks associated with storage systems	Persistent enforcement of regulations in all types of regions (high and low renewable concentration)	Monitor progress of regulations and provide feedback for improvement in methodologies of local utility	Identification and continued enforcement of key regulations
Scenario modeling	Develop models for accurate forecasting of resource accessibility, demand, dispatch capabilities, pricing, and reliability	Identify incremental (smart grid, nuclear) and detrimental (EV, storage) technologies, in terms of grid operational risk	Demonstration of effects of best- and worst-case scenarios on supply/demand, technological development, and capital costs	Identification of relevant scenarios that will help guide the future development of potential storage technologies
Contribution: utility and public	Development of customer and utility actions for propagation of the renewable agenda	Assessment and regulated enforcement of utility enforced actions (e.g., price incentive for customers, storage management)	Assessment of potential customer actions (e.g., use of energy efficient devices)	Identification of low-risk actions for the utility and the customer
Reliability assessment	Develop current, short- and long-term assessment roadmap for risks associated with storage integration	Identify key factors affecting reliability of storage systems (e.g., variability, ramping requirements, peak mismatch)	Develop plan to proportionally increase integration of low-risk storage systems, with increasing demand, to achieve higher base-load penetration	Studious development of reliability risks and solutions for potential storage technologies

100 KJ/cm³ may be possible. If very high energy densities are achieved, these supercapacitors may replace batteries in EVs. There are a variety of materials with which very high dielectric constants can be obtained but there is a great deal of work to be done before these supercapacitors become available for EVs [28].

Recommendations for Future Work

Various applications and options discussed in this entry are still in the development phase

and therefore are not “grid-ready.” Current progress in the energy storage sector is limited to fulfillment of functional specifications only. Grid storage solutions are a long term goal for this sector. To develop these solutions, short-term goals need to include fundamental research, analysis, testing, evaluation of risk, and demonstration of technology. Table 12 is considered a starting point for the fulfillment of short- and long-term goals.

Glossary

Bike lane A special road lane reserved for bikes only, usually about 4–6 ft wide, normally located on the right-hand side of the road.

Bike locker A box-like metal or plastic container for secure bike storage, often at rail stations, usually rented on a monthly basis.

Bike rack A device on which bikes can be mounted for transport (on buses) or attached for storage and security (on sidewalks).

Bike station Full-service, secure bike parking facility, usually providing repair and rental services, accessories, and touring advice.

Bus Motorized coach services providing communal transport on roads, usually in mixed traffic, but sometimes as part of special bus rapid transit (BRT) systems with separate rights of way.

Light rail Type of rail system similar to streetcars (trams) but often with separate right of way over at least part of its route, special boarding stations, and pre-paid fares.

Metro Urban rail system with separate rights of way, frequent service, and high carrying capacity, usually found only in large cities.

Public transport/transit General term for communal transport in cities, including buses, trams, trolleys, light rail, metros, suburban rail, ferries, and funiculars.

Suburban rail Short-distance passenger rail systems connecting large cities with their surrounding metropolitan areas, with longer distances between stops and less frequent service than metro systems.

Definition of the Subject and Its Importance

Coordinating bicycling with public transport is mutually beneficial, enhancing the benefits of both modes and encouraging more bicycling as well as more public transport use. Bicycling supports public transport by extending the catchment area of transit stops far beyond walking range and at much lower cost than neighborhood feeder buses and park-and-ride facilities for cars. Access to public transport helps cyclists make longer trips than possible by bike. Transit services can also provide convenient alternatives when cyclists encounter bad weather, difficult topography, gaps in the bikeway network, and mechanical failures.

Introduction

The overall importance of both bicycling and public transport in northern Europe has provided a strong rationale for coordinating these two modes of urban transport in recent decades [1]. European studies find that coordinating bicycling with public transport is mutually beneficial, enhancing the benefits of both modes and encouraging more bicycling as well as more public transport use [2–8]. In the Netherlands, 35% of all rail passengers reach their stations by bike – compared to 25% in Denmark and 9% in Sweden [1].

The main form of bike-transit integration in Europe is bike parking at suburban train and metro stations [1]. In the Netherlands, there are 350,000 bike parking spaces at train stations. German cities also have extensive bike parking at rail stations. The City of Berlin, for example, has over 32,000 bike parking spaces at its metro and suburban rail stations [9]. By comparison, no city in North America has more than 15,000 bike parking spaces of any kind, let alone at public transport stops.

The most impressive bike-and-ride facilities in Europe are state-of-the-art “bike stations,” which

provide secure, sheltered parking as well as a wide range of services such as bike repairs, accessories, washing, rentals, and travel advice. In 2007, there were 67 bike stations in the Netherlands, 70 in Germany, and 20 in Switzerland, almost always located adjacent to train stations to facilitate bike-and-ride [1, 5, 10–12]. As noted later in this entry, there are only ten bike stations in all of North America, and they are much smaller than those in Europe.

North America obviously lags behind Europe in the integration of bicycling and public transport. In the past, bike-and-ride in North America was limited by low overall levels of cycling and public transport use in most cities, just the reverse of the situation in northern Europe [1, 5, 12, 13]. In recent years, however, both cycling levels and public transport use have risen sharply in the USA and Canada, and bike-and-ride trips have been increasing as well. Indeed, in some cities it has been so successful that the demand for bike-and-ride facilities exceeds the available supply [14, 15].

This entry describes the programs and policies currently being implemented in North America to integrate bicycling with public transport. It starts off with a brief overview of the various kinds of integration and the extent of their implementation. Most of the entry, however, is devoted to case studies of bike-transit integration in two large cities in Canada (Toronto and Vancouver) and six large cities in the USA (San Francisco, Portland, Minneapolis, Chicago, Washington, DC, and New York City). The case study analysis compares the type and extent of integration measures undertaken in the various cities, noting the strengths and weaknesses of each city's integration policies. The entry concludes by identifying the most innovative and successful policies in the eight cities and offers policy recommendations for future improvements.

Trends in Bike-Transit Integration

In recent years, levels of cycling and public transport use have reached record highs in both the USA and Canada. In 2008 public transport use in the USA was at its highest level since the early 1960s [16, 17]. Between 1995 and 2008, public transport trips rose by 38% in the USA and by 46% in Canada [17, 18]. Similarly, levels of cycling have increased considerably since

1990. In the USA the total number of bike trips to work increased by 32% from 1990 to 2005–2007 (averaged) [19, 20]. Over the shorter period 1996–2006, the number of bike trips to work in Canada rose by an even larger 42% [21].

While rising public transport use and increased cycling have provided the rationale for more bike-transit integration, federal funding in the USA has provided the necessary financing for a wide range of projects implemented in recent years at the state and local government levels [14, 15, 22, 23]. Indeed, the federal government finances some categories of bike-transit integration projects with an especially high 95% federal share. The integration of public transport with cycling has been endorsed by the Federal Transit Administration, the Federal Highway Administration, and the Transportation Research Board [14, 15, 24]. The Transport Association of Canada [25] and Transport Canada [26] have also endorsed bike-transit integration, but there is no federal funding for urban transport in Canada. There is no federal funding for urban transport in Canada, but provincial and local governments have provided large increases in funding for public transport and bicycling in recent years, including projects aimed at better integration [27, 28].

As documented in this entry, virtually every large city in the USA and Canada has been undertaking a range of measures to promote bike-and-ride. There are five main categories of measures to promote bike-transit integration:

- (a) Provision of bike parking at rail stations and bus stops, with different degrees of shelter and security
- (b) Multifunctional bike stations providing not only parking but also a range of services such as bike rentals, repairs, parts and accessories, bike washing, showers and lockers, and touring advice
- (c) Bike racks on buses, usually exterior, but occasionally interior storage
- (d) Bikes on board vehicles, usually rail vehicles, sometimes with special bike racks, hooks, or even bike cars on trains
- (e) Bike paths, lanes, and on-street routes that lead to public transport stations and stops, thus facilitating the bike's role as feeders and collectors for public transport

Extent of Bike-and-Ride Facilities in North America

The only available national statistics on bike parking at public transport stops are from recent surveys of 272 American and Canadian transit systems by the American Public Transportation Association [29, 30]. In the USA, the supply of bike parking spaces in 2008 was 24,178 at rail stations, 9,005 at bus stops, and 176 at ferry terminals. For the same year, Canadian systems reported 2,892 bike parking spaces at rail stations and 481 at bus stops. Between 2006 and 2008, the supply of bike parking increased by 67% in Canada and 26% in the USA [29, 30]. That is impressive progress, but it is striking that in 2008, the total supply of bike parking at public transport systems in the entire USA was only slightly more than the 32,000 spaces in Berlin, Germany [9].

Not only is there much less bike parking in North America, but it is far less likely to be sheltered and/or guarded. Throughout northern Europe, there has been a trend toward sheltered, guarded bike parking, usually outdoors but increasingly in bike stations [1, 5, 9, 12, 31, 32]. By comparison, unattended bike lockers are the main form of secure bike parking at North American public transport stops. Of the 56 large American and

Canadian transit systems surveyed by the Transportation Research Board [15], 14 systems provided bike lockers at some of their rail and bus stops, but the actual number of lockers was not reported. The same TRB survey reported eight staffed bike parking stations in 2005, mainly on the West Coast. A few more bike stations have opened since then [10].

By far the most important form of bike-transit integration in North America is bike racks on buses. Indeed, on this dimension, North America is far ahead of Europe, where very few buses come equipped with bike racks. That is not surprising since 60% of all public transport trips in the USA are by bus [18]. Bike racks are inexpensive to install, easy to operate, and do not take up space on the vehicles themselves [15]. The 2005 TRB survey found that systems throughout the USA and Canada provide bike racks on buses, and that most systems have eliminated fees they had previously charged for rack use. As shown in Fig. 1, the percentage of buses with bike racks almost tripled in the USA in only 8 years, from 27% in 2000 to 72% in 2009 [30, 33]. Since 60% of all public transport trips in the USA are by bus, it is understandable that the focus of bike-transit integration efforts in North America has been on bus-bike racks [18, 33]. They are inexpensive to install, easy

Bicycle Integration with Public Transport. Figure 1

Trend in percentage of buses with exterior bicycle racks in the USA, 2001–2009 [18]

to operate, and do not take up space on the vehicles themselves [15].

Another important form of bike-transit integration is the permission to take bikes on board public transport vehicles, since that enables cyclists to ride their bikes to and from public transport stops at both ends of their trips. Few public transport systems permit bikes to be taken on board buses unless they are compact, folding bikes. But most systems permit bikes on light rail, metro, and suburban rail trains, except during peak hour periods when crowding makes this infeasible [15]. Moreover, an increasing number of public transport systems are providing special accommodations for bikes on trains, such as bike racks, bike hooks, special bike holding areas near the doors, and even special bike cars – although rarely [15, 33].

The last aspect of bike-transit integration is the coordination of bike routes with public transport stops. There are no national statistics available on the extent of implementation, and it would be hard to

quantify at any rate. Nevertheless, the eight case studies qualitatively assess this aspect of bike-transit integration in each of the cities.

Case Studies of Bike-Transit Integration

All eight of the case study cities are large, but they vary considerably in metropolitan area population, ranging from 2.2 million in Portland, Oregon, to 18.2 million in New York City. The cities also vary widely in their geographic locations, climate, and topography. Most important for this study, they vary greatly in the share of trips covered by bicycling and public transport, as shown in Figs. 2 and 3.

In 2006, public transport shares of work trips for central city residents ranged from only 13% in Portland to 55% in New York (Fig. 2). Public transport trip shares for metropolitan areas ranged from 5% in Minneapolis to 30% in New York. The Canadian cities of Vancouver and Toronto have relatively high public

Bicycle Integration with Public Transport. Figure 2

Public transportation share of work trips in US and Canadian cities and metropolitan areas, 2006/2008 [20, 34]

Bicycle Integration with Public Transport. Figure 3

Bicycling share of work trips in US and Canadian cities and metropolitan areas, 2006/2008 [20, 34]

transport use for their intermediate size. Indeed, their metropolitan areas have higher public transport mode shares than the Chicago area. Other studies confirm that, controlling for population size, Canadian cities have slightly more than twice as many public transport trips per capita as American cities [35, 36]. Without exception, public transport use is higher in all eight central cities than in their suburbs. The difference is far smaller in Toronto and Vancouver than for the American cities, because of the higher density of Canadian suburbs as well as the greater provision of public transport services there [35, 36].

Levels of cycling also vary greatly among the eight cities (Fig. 3). Portland (6.0%) and Minneapolis (4.3%) had the highest bike mode shares of work trips in 2006, but Vancouver (3.0%) and San Francisco (2.7%) were not far behind. By comparison, cycling to work in New York (0.6%) and Chicago (1.0%) is rare. Similar to levels of public transport use, bicycling is

much higher in central cities than in the suburbs. The differences for Canadian cities, however, tend to be smaller than for American cities, and the reason, again, is the much higher density of Canadian suburbs vis-à-vis American suburbs [28].

There are no comparable statistics on levels of bike-and-ride in each of these cities, since the most recent American and Canadian national travel surveys only report the main mode of transport for the work trip. Figures 2 and 3 provide useful background, however, by portraying the overall levels of cycling and public transport in the eight cities and their corresponding metropolitan areas. On the basis of European experience, it would seem that the higher the levels of both cycling and public transport use, the greater the potential for bike-transit coordination. On the other hand, where there are large imbalances between the two modes, it might suggest that the modes substitute for each other rather than complement each other. For example, the

extremely low level of cycling in New York might be partly due to a high level of public transport use. Conversely, Portland and Minneapolis, the cities with the highest bike mode shares, have the lowest public transport mode shares, suggesting that some bike trips might substitute for public transport trips. There are many possible explanations for the different levels of cycling and public transport use, but a detailed analysis is beyond the scope of this entry, which is limited to the more modest goal of examining the nature and extent of bike-and-ride programs in these eight case-study cities [1, 4, 5, 7].

Efforts to integrate cycling with public transport vary greatly among the eight case studies. New York City, for example, has done little to promote bike-and-ride, while San Francisco, Vancouver, and Portland have implemented the entire gamut of integration measures. The following section highlights the most important aspects of bike-and-ride policies in each city, noting in particular the strengths and weaknesses of current policies.

Unless otherwise indicated, the information for these case studies was obtained by the authors directly from bicycling planners, public transport systems, metropolitan planning organizations, city transport departments, and nongovernmental cycling and sustainable transport organizations in each metropolitan area. The same panel of transit and cycling experts also reviewed the case studies of their cities at several stages to check for accuracy, consistency, and completeness.

San Francisco

The San Francisco Bay Area has been a leader in bike-transit integration efforts in North America. Its regional metro system Bay Area Rapid Transit (BART) provides bike parking at almost all 43 stations, with a total of 4,313 bike parking spaces in 2009, including 1,010 in secure bike lockers. In order to increase convenience and flexibility, BART has been introducing electronic bike lockers (294 as of 2009), which are available on a first-come, first-serve basis and do not require advance subscriptions. Caltrain, the suburban rail line from San Francisco south to Palo Alto and San Jose, provides bike parking at all 32 stations, with a total of 1,100 bike lockers and 400 bike racks.

The San Francisco Bay Area had five of the ten bike stations in the USA in 2009: 226 bike parking spaces at two Caltrain stations and 433 spaces at three BART stations. The BART and SF Caltrain Bike Stations provide free, attended bicycle parking, while the Palo Alto facility is an unattended, fee-based garage. Utilization rates of the bike stations vary widely, from over 100% at the Berkeley BART station to only 11% at the Palo Alto Caltrain station. BART will soon triple the size of the Berkeley bike station and move it above ground to increase accessibility.

Cyclists prefer to take bikes on board, however. A 2008 survey found that 72% of bike-and-ride passengers carried their bikes with them, compared to only 28% who parked them at BART stations. Bikes are allowed on BART trains except during peak hours in the peak direction. Although Caltrain has no time restrictions, cyclists are often denied boarding on rush hour trains because all bike spaces are already occupied. Neither BART nor Caltrain charge a fee for bringing bikes on board. Moreover, Caltrain's lead cars provide special accommodations for 16–32 bikes, depending on time of day and direction of travel. Most of the numerous ferry lines in the Bay Area also permit bikes on board with no extra fee. Folding bikes are allowed on BART and Caltrain at all times, but are not permitted on board San Francisco's MUNI buses, streetcars, cable cars, and light rail vehicles. Complementing bike access to BART and Caltrain services, virtually all buses of all public transport systems in the San Francisco Bay Area are equipped with bike racks, free of charge to cyclists.

There is limited coordination of bike routes with public transport routes. To avoid bus-bike conflicts, bike routes are not usually located on bus routes in San Francisco, but are on parallel streets. Due to the extensive and fine-grained network of bus and rail routes in San Francisco, bike routes often lead to public transport stops, even without any explicit coordination. The Regional Bicycle Plan as well as the Bike Plans of BART and Caltrain explicitly encourage coordination of bike routes and facilities with public transport. Outside of San Francisco, where public transport routes and stations are farther apart, many communities make an explicit effort to coordinate bike routes with key stops.

Overall, bike-transit integration efforts in the San Francisco Bay Area have been successful.

The percentage of public transport trips combined with cycling has more than tripled since 1990. Nevertheless, several problems remain. For example, it is difficult for cyclists to get across the San Francisco Bay during rush hours, since bikes are prohibited from BART trains in peak directions and not permitted on the Bay Bridge. Similarly, Caltrain has problems accommodating bikes on board in the peak hour and often denies boarding to cyclists. The exclusion of bikes from Muni's light rail lines is also a problem for cyclists. Overall, however, the available evidence suggests that bike-transit integration efforts have been successful.

Portland

As shown in Fig. 2, Portland has the highest bike share of work trips of any large American city (6.0%). Thus, one would expect a high degree of bike-transit coordination. Bike-and-ride in Portland, however, is quite different from that in San Francisco and mainly involves bikes on transit vehicles. TriMet, Portland's public transport system, estimates that ten times more bikes are taken on their LRT vehicles than parked at LRT stations (2,100 vs. 200 per weekday). There are no fees, no permit requirements, and no time of day or directional restrictions for taking bikes on LRT vehicles. Every train has a low-floor car especially designed to facilitate bike access, with waiting areas and four bike hooks located near the doors. But passengers without bikes have priority to board crowded trains. All buses in the Portland area have bike racks, another inducement for cyclists to ride with their bikes instead of parking them.

By comparison, Portland does not provide much bike parking at train and bus stops. In 2009, there were a total of 670 bike parking spaces at TriMet LRT stops and transit centers (major transfer hubs for several bus or LRT lines). Of those, almost half were bike lockers. In addition, there were city-owned bike lockers at 15 locations in downtown Portland, most of which are near bus or rail services. In sharp contrast to San Francisco, Portland does not have any bike stations, which is surprising given its high bike mode share and wide range of other pro-bike policies and programs. Bicycling planners and public transport officials in Portland plan to improve bike parking at transit stops by installing 196 bike lockers and 168 bike racks at LRT extensions.

Portland cyclists prefer taking their bikes on board transit vehicles. A survey by TriMet indicated that 76% of cyclists would not be willing to park their bikes at a transit stop even if there were sheltered and secure bike parking available. The advantage of taking bikes on buses or rail vehicles is that bikes can then be used at both ends of the transit trip. So the aversion to parking bikes at bus and rail stops may be due more to convenience than to concerns over theft or vandalism.

Portland carefully and explicitly coordinates its bikeway network with its public transport network. The city has set the goal of a seamless link between cycling and transit. Bike routes are designed to facilitate access to public transport stops. Most transit centers are served by multiple bikeways. Moreover, city planners give special consideration to enhancing bike access to transit stops in outlying areas too far away from the city center for most people to cover by bike alone. Nevertheless, as in most cities, there are some public transport stops that are difficult or dangerous to access by bike. As the largest of America's three platinum level Bicycling Friendly Communities, Portland has already made impressive progress at integrating cycling with public transport and seems sure to continue on that path.

Vancouver

Similar to San Francisco and Portland, Vancouver has vigorously promoted the integration of public transport and cycling. The unique advantage in Metro Vancouver is TransLink, the fully integrated, multimodal regional transportation authority. Unlike the other case studies, public transport, major roadways, and bicycling in Vancouver are all handled within the same agency. The coordination of cycling and public transport is obvious and natural in such a multimodal agency – as reflected in TransLink's plans, funding, construction projects, vehicle procurement, and operating procedures. Over the past 10 years, TransLink has spent over \$12 million specifically on bike-transit integration.

As in the San Francisco and Portland areas, all buses in Metro Vancouver are equipped with bike racks. Similar to San Francisco's BART, bikes are allowed on Vancouver's SkyTrain except during peak hours in the peak direction due to problems of overcrowding. Until recently, there were no special accommodations for

bikes on SkyTrains, but all future vehicles will provide a special area for bikes in the rear of each car with a leaning rail and fold-up seats. Bikes are allowed at all times on West Coast Express trains for a \$.50 charge. SeaBus ferries permit bikes on board at all times without charge. Almost all of TransLink's rail and ferry services are fully accessible – through elevators, ramps, or level boarding – thus facilitating bike-and-ride.

There are bike racks at all SkyTrain and West Coast Express rail stations as well as park-and-ride lots and transit nodes with interchanges of several bus or rail lines. In 2008, Vancouver had a total of 1,060 parking spaces at transit stops: 660 spaces in racks and 400 secure bike lockers. TransLink plans to increase the overall supply of bike parking at transit stops in the coming years, with a special focus on improving the quality of bike parking, especially secure short-term bike parking. Bike stations at the most important transit hubs are also being considered.

Thanks to its multimodal orientation, TransLink explicitly coordinates bike routes with public transport. For example, the construction of the Millennium, Expo, and Canada SkyTrain lines included traffic-protected, parallel bike routes to foster bicyclist access to public transport. Another aspect of TransLink's multimodalism is the focused promotion of cycling in central corridors where bus and rail vehicles are the most crowded, and where cycling has the potential to divert some of the overload and thus reduce crowding. That coordination of demand and supply between the two modes is rare and emphasizes the advantages of multi-modal agencies such as TransLink.

Minneapolis

Although Minneapolis is, by far, the coldest of the eight cities, it has the second highest bike share of work trips after Portland (4.3% vs. 6.0%). Public transport's share of work trips is slightly higher in Minneapolis than in Portland (13.4% vs. 11.2%), but much lower than in any of the other cities (Fig. 2).

Metro Transit had 497 bike parking spaces at its light rail and bus stops in 2007: 271 spaces in bike racks and 226 bike lockers. Minneapolis has a staffed bike station, the Midtown Bike Center, with 100 bike parking spaces, repairs, rentals, and a café. It is only

a block from the Chicago and Lake Streets transit hub, which serves two of the city's busiest bus lines. Perhaps the city's most ingenious policy is the official designation of 35,000 traffic sign posts as bike parking with 70,000 bike parking spaces, assuming two bikes parked at each post. The city also considers that a form of bike-transit integration, since many traffic sign posts are near bus stops, including the bus stop post itself.

All Metro Transit and suburban transit buses are equipped with exterior bike racks, and the city has five stationary bike racks for first-time users to practice loading their bikes. Every light rail vehicle has interior vertical racks that accommodate four bikes. Bike-and-ride has become increasingly popular in Minneapolis. Metro Transit surveys in spring 2007 and fall 2008 found a doubling in the number of bicycles transported on bus racks and a 41% increase in bikes on light rail. On an average weekday in 2008 Metro Transit buses carried 870 bikes. Only 4% of cyclists had to wait for another bus due to racks being filled.

There is no explicit policy of coordinating bike routes and transit stops in Minneapolis, and city officials emphasize the need to improve cycling facilities feeding into public transport stops. Some bike routes already lead to transit stops or parallel transit lines. For example, the Hiawatha LRT line runs parallel to an off-street bike path for most of its length in Minneapolis, thus providing an alternative for cyclists on that route.

Chicago

With the second largest transit system in the USA, Chicago has made impressive efforts to integrate cycling with public transport. Its special distinction lies in the innovative provision of bike parking at rail stations, tailoring the design of parking facilities to each station's particular situation. With 6,420 parking spaces at its rail stations, Chicago has about the same amount of bike-and-ride parking as the San Francisco Bay Area, and far more than other cities in North America.

There are 2,153 bike parking spaces at 131 of the 143 CTA subway and elevated rail stations and 4,267 spaces at 50 of the 76 Metra suburban rail stations. Moreover, indoor or sheltered parking is available at 83 CTA stations, more than any other transit system in North America. The specific location of bike racks inside the stations provides both weather protection and greater

security, since they are usually placed within easy sight of station attendants and other passengers. Chicago is currently installing additional sheltered bike parking for 382 bikes at four CTA stations, and the city has funding to install bike shelters for 250 more bikes in 2010.

The largest bike station in the USA is located in Chicago's Millennium Park, immediately above the terminal station for two of Chicago's suburban rail lines. The bike station is easily accessible from downtown Chicago and the 18-mile Lakefront Trail. It provides secure, indoor parking for 300 bikes as well as convenient lockers, showers and towel service, bike rentals, bike repairs, and guided bicycling tours.

The CTA regularly monitors bike parking needs by conducting bi-annual bike rack inventories and measuring usage rates. It then works with Chicago DOT to install additional racks where needed.

As in most of the case study cities, all of Chicago's buses have bike racks – including CTA buses as well as PACE suburban buses. Bikes are permitted on CTA and Metra trains except during weekday rush hours. And just as most of the other cities, no fees or permits are required for the use of bike racks on buses or for bringing bikes on trains.

The biggest challenge to bike-transit integration in Chicago is the difficult access to train platforms. Because most of the rail lines are so old, only 54% of CTA stations and 68% of Metra stations are ADA accessible. Thus, cyclists are often forced to carry their bikes up long flights of stairs. Few stations have elevators, and cyclists are not permitted to use escalators.

Chicago DOT, transit agencies, and the cycling community are aware of these problems and have made improvements in bike-transit integration a top priority. Chicago's Bike Plan 2015 sets goals of further expanding and improving bike parking inside and outside of rail stations, remodeling stations to make them more accessible to bikes, providing more park-and-ride facilities, and establishing a second bike station with better transit connections.

Toronto

The combination of high rates of transit use and rising cycling levels has prompted a range of efforts to integrate the two modes in the Toronto metropolitan area. The

main approach has been to provide ample bike parking. With over 15,000 post-and-ring bike racks throughout the city, Toronto has more bike parking than any other city in North America. That includes bike parking at almost all rail stations. In 2008, there were 1,192 short-term spaces in bike racks at Toronto Transit Commission (TTC) subway stations and 579 short-term spaces in racks at GO Transit suburban rail stations.

Yet there is a severe shortage of secure bike parking, with only 114 bike lockers in the entire transit network. Consequently, Toronto plans on greatly expanding the supply of secure parking in 2009 and 2010 through installation of more bike lockers and completion of a new bike station at Union Station, the main transit hub in downtown Toronto, providing bus, streetcar, subway, and suburban rail connections. The bike station will provide secure, sheltered parking for 200 bikes. Construction of an even larger bike station at City Hall is planned to begin in 2010. That facility will be close to several bus and streetcar lines. The GO Transit suburban rail system is improving its bike parking by expanding sheltered parking to all stations by the winter of 2009–2010.

As in most cities with high levels of rail transit use, bikes cannot be taken on TTC subways and streetcars during weekday peak hours. Even when permitted, there are no special provisions for bikes on TTC subway cars. Similarly, bikes are not allowed on any GO Transit trains headed toward Union Station in the morning peak (6:30–9:30) or departing Union Station in the evening peak (3:30–6:30). Folding bikes are permitted on all public transport vehicles at all times. Bike access to rail transit is limited by the lack of elevators in most subway stations. As in Chicago, cyclists in Toronto must carry their bikes up and down long flights of stairs to reach the train platforms. Only 41% of TTC subway stations are wheelchair accessible, while 75% of GO Transit stations are accessible, either through elevators or ramps.

Toronto is making rapid progress equipping its buses with bike racks, which can be used at any time, even during peak periods. In 2008 only 55% of TTC buses had bike racks, but all new buses have racks, and every month about 40 older buses are retrofitted with racks. By the end of 2010, all TTC and GO Transit buses will have bike racks, thus facilitating bike and ride throughout the region.

There is almost no explicit coordination of bike routes with transit routes and station stops. Instead, the guiding principle of bike route planning is to put every Torontonians within a 5-min bike ride of the bikeway network. The many transit stations and fine-grained street network in much of the central city facilitates bike access to TTC stations. In suburban areas, however, many streets are circuitous and do not connect across arterials, making it difficult for cyclists to avoid major arterials while en route to a transit station.

Although bike-transit integration in Toronto faces some serious challenges, much progress is being made, partly thanks to the Province of Ontario's Metrolinx BikeLinx Program, which helps finance bike parking at stations and bike racks on buses. With the two new bike stations, additional bike lockers, expansion of sheltered parking, and completion of bike rack installation on all buses by 2010, Toronto will have made great strides coordinating cycling and public transport.

Washington

Bike-transit integration in Washington is similar to the situation in the San Francisco Bay Area. Both metropolitan areas rely on regional metro systems started in the late 1960s and early 1970s: BART in San Francisco and Metrorail in Washington. There is bike parking at almost all of Washington's 86 Metrorail subway stations, with a total of 1,800 bike racks and 1,300 bike lockers. The parking facilities are popular, with usage rates at most stations ranging from 50% to 100%. In October 2009, a new bike station with spaces for 150 bikes will open next to Union Station, providing convenient connections to Metrorail as well as suburban trains leaving from Union Station. The bike station will also offer bike rentals, repairs, and accessories as well as storage lockers and changing rooms.

In 2008 a new bike sharing program began in Washington, similar in technology to the Velib system in Paris, but on a much smaller scale: only 120 bikes compared to over 20,000 bikes in Paris. It facilitates bike-and-ride because eight of the ten bike sharing docking stations are at Metrorail stops. The short-term rental bikes can be used to get to and from Metrorail stations, thus serving as feeders and distributors for transit.

Bikes are allowed on Metrorail trains except during morning and afternoon rush hours on weekdays: two bikes per car on weekdays, four bikes per car on weekends. Unlike the much older subway systems in New York and Chicago, all 86 Metrorail stations have elevators (271 in total) and are ADA accessible. That facilitates access to platforms for cyclists as well, who are, in fact, required to use the elevators and are not permitted on escalators. In contrast to the Metrorail, VRE and MARC suburban trains do not allow bikes on board at any time unless they are folding bikes. All 1,450 WMATA buses have bike racks, but some buses run by suburban agencies do not.

In theory, bike plans for the Washington area establish the goal of coordinating bike routes with transit routes, but in fact, nothing has really been accomplished in this area except by accident. Overall, however, bike-transit integration in the Washington area is successful. The biggest gap is the exclusion of bikes from the Metrorail system during peak hours. To some extent, this is unavoidable due to the overcrowding of metro cars, just as on the BART, Toronto, and Chicago subway systems. But it reinforces the need to expand bike parking at the many Metrorail stations where current capacity is insufficient.

New York/New Jersey

With 55% of all work trips by public transport, New York City has, by far, the highest transit mode share of any city in North America. Thus, one might expect substantial efforts to coordinate cycling with public transport. In fact, New York City's transit systems have done little to promote bike-transit integration, far less than any other city in this study. The Metropolitan Transportation Authority (MTA) does not provide bike parking of any kind at the city's 467 subway stations, so the only option for cyclists is to park on nearby sidewalks. The MTA's suburban railroads, the Long Island Railroad (LIRR) and Metro-North Railroad (MNR), offer bike parking at some of their stations – but MTA has no information on the total number of spaces (MTA, 2009).

Compounding the problem of insufficient bike parking along the many subway and suburban rail lines of the MTA, there is no secure bike parking at any public transport terminals in Manhattan. Train, bus, and ferry terminals do not even offer short-term

parking in bike racks. Thus, cyclists must seek out the occasional bike rack on sidewalks within a few blocks of the terminals or risk having their bikes confiscated if parked at traffic signposts, which is illegal in New York.

NYC subways are unique in permitting bikes on board trains at all times, but it is difficult to get bikes to the platforms. Only 16% of New York's subway stations are ADA accessible via elevators or ramps. At the remaining 84% of stations, cyclists must carry their bikes up and down long flights of stairs, as they are prohibited from using escalators in stations where they are available. Bikes are allowed on the MTA's two suburban railroads (MNR and LIRR) except during peak hours in the peak direction, but cyclists must register in advance and purchase \$5 lifetime permits. Folding bikes are allowed at all times. In 2008, 18% of LIRR stations and 52% of MNR stations were not ADA accessible – considerably less than the 84% inaccessible MTA subway stations, but still a problem for cyclists having to carry their bikes up and down stairs.

Bike-bus integration is almost non-existent in New York City. Not a single bus in the MTA's fleet of 5,929 buses has a bike rack. That contrasts sharply with 100% of buses equipped with bike racks in most of the other case-study cities. Only since spring 2008 have folding bikes been allowed on most MTA buses.

There is no explicit effort to coordinate bike routes with transit routes in New York City. That is not a severe problem in most of the city because the transit network is so dense that most neighborhoods are served by a nearby subway or bus line. In the suburbs and the outermost portions of the city, however, the complete lack of bike-transit route integration is a serious shortcoming. Precisely in those lower density areas where cycling would provide an ideal feeder mode to more distant transit stops, bikeways are almost exclusively recreational paths that do not connect to practical destinations such as transit stations.

Not only does New York compare unfavorably in its bike-transit integration to the seven other case study cities, but it is surpassed by the New Jersey portion of the Greater New York metropolitan area. In 2008, New Jersey Transit (NJT) offered bike parking at 90% of its suburban rail stations and 80% of its light rail stations, with a total of 2,400 spaces, including 376 secure bike

lockers. Unlike the MTA in New York, NJT provides bike racks at all three of its major terminals in Hoboken and Newark (Penn Station and Broad Street). Bikes are allowed on all suburban rail and light rail lines except during rush hours in the peak direction, and no permits or fees are required. Folding bikes are allowed on all NJT vehicles at all times. Roughly half of NJT's 2,000 buses are equipped with bike racks, and an additional 200 buses are outfitted with racks each year. By 2014, 95% of NJT's buses will have bike racks. The main problem in New Jersey is the almost complete lack of bike paths and lanes leading to NJT rail stations and bus stops.

Summary of Case Studies

Most of the case study cities have greatly improved the coordination of bicycling and public transport in recent years. They have increased bike parking at transit stops and better accommodated passengers wanting to take their bikes with them on buses and rail vehicles. Only a few transit systems have measured the actual extent of bike and ride, but the available evidence is encouraging. In Washington DC, for example, the number of bicyclists riding on Metrorail increased by 60% between 2002 and 2007. At some stations, cyclists accounted for up to 4% of all passenger boardings. In Minneapolis, Metro Transit carries over 250,000 bicycles annually and reports a doubling of bikes on buses between spring 2007 and fall 2008. Roughly 4% of Portland MAX light rail passengers carry their bikes onto the vehicles with them. In the San Francisco Bay Area, the share of passengers accessing BART stations by bike rose from 2.5% in 1998 to 3.5% in 2008, with an average of 10,920 bike-and-ride trips per day.

As shown in [Table 1](#), there is considerable variation among the eight case studies. The San Francisco Bay Area, for example, provides the full gamut of bike-integration measures and has been at the vanguard of innovations to promote bike-and-ride. By comparison, New York's transit systems have made few provisions to accommodate cyclists, lagging behind the other case study cities in both the quantity and quality of bike-integration measures. All eight of the cities have plans to further improve bike-transit integration. Thus, it seems certain that the promising trends of recent years will continue.

Bicycle Integration with Public Transport. Table 1 Overview of bike-transit integration measures in eight large American and Canadian cities [37–54]

Bike parking at transit stops and stations	Bikes on transit		Bike routes and transit stops	Highlights: strengths and challenges
	Bike racks on buses	Bikes on trains		
San Francisco (population city: 0.8 m, metro: 4.2 m)				
BART provides 4,313 bike parking spaces, including 716 conventional and 294 electronic bike lockers	All buses have bike racks (usage rates vary from 17% to 43%)	BART allows bikes on all non-peak trains and during peak times in non-peak directions. BART expanded on-board space for bikes on select cars	Bike routes often parallel MUNI bus routes and intersect with transit stops. No explicit planning process coordinating transit and cycling routes in SF	Strengths: Racks on all buses; extra space for bikes on Caltrain cars; bike access to BART off-peak; extensive bike parking at BART and Caltrain stations; five bike stations
Caltrain's 32 suburban rail stations offer 400 bike racks and 1,100 bike lockers		Caltrain: special lead cars designated for bike use all day, space for 16–32 bikes	The Regional Bicycle Plan as well as the Bike Plans of BART and Caltrain encourage coordination of bike routes and facilities with public transport	Challenges: No bike access on MUNI light rail; need more dedicated space for bikes on Caltrain; no coordination of bike routes with MUNI routes; no rush hour access for bikes on BART
Five bike stations with 659 bike parking spaces at BART and Caltrain Stations				
Portland (population city: 0.5 m, metro: 2.1 m)				
Bike racks and/or lockers at almost all TriMet LRT stops and transit hubs providing 670 bike parking spaces; including 320 secured spaces	All buses have bike racks	MAX light rail: bikes permitted if space is available on cars, but non-cyclists passengers have priority	Explicit coordination of bike routes with transit stops with the goal of establishing a seamless link between the two modes	Strengths: Racks on all buses; dedicated space on LRT for hanging bikes near doors; free access for bikes 24/7; easy access to low-floor trains
15 downtown locations with bike lockers; usually close to light rail or bus stops				Challenges: Lack of good quality and quantity of parking at most train stations; poor design of access to stations by bike; cyclists are often denied boarding on LRT during peak
Vancouver (population city: 0.6 m, metro: 2.1 m)				
660 bike parking spaces in bike racks at SkyTrain stations and at transit transfer nodes	All buses have bike racks	SkyTrain: bikes allowed anytime except in peak periods in peak direction	Central Valley Greenway and BC Parkway facilitate access to and from transit stations	Strengths: Bike racks on all buses; bikes allowed on SkyTrain except during peak hours in peak direction; integration of bike network and transit stops; bike parking at all major transit stops; 24/7 no cost bike access on SeaBus
400 secure bike lockers at most Sky Train and all West Coast Express stations		SeaBus: bikes allowed at all times	Translink's \$2.55 million annual cost sharing of cycling infrastructure favors projects that facilitate access to transit	Challenges: Need more and better bike parking; need more capacity on SkyTrain to accommodate cyclists

Bicycle Integration with Public Transport. Table 1 (Continued)

Bike parking at transit stops and stations	Bikes on transit		Bike routes and transit stops	Highlights: strengths and challenges
	Bike racks on buses	Bikes on trains		
Minneapolis (population city: 0.4 m, metro: 3.2 m)				
271 bike parking spaces and 226 bike lockers next to Metro Transit stops and at park-and-ride lots. Usage rate of 28% of bike parking spaces at Hiawatha LRT line	All buses have bike racks. Bike on bus demonstration racks in various locations	27 light rail vehicles with on-board interior vertical racks that accommodate 4 bikes per vehicle	No explicit coordination of bike routes and transit. But connection to transit lines is a prioritizing criterion for bike projects funded by the MPO	Strengths: Bike racks on buses and trains; bike racks and lockers at most train stations; marketing information on bike transit integration provided by Metro Transit
City bicycle ordinance encourages parking bikes at sign posts, which are within a block of most bus stops. Bike station 1/10 of a mile from the Chicago and Lake Street transit hub			The Hiawatha LRT line parallels an off-street bike path for most of its length in Minneapolis	Challenges: Bike racks needed at four more LRT stations; lack of bike paths and lanes leading to train stations and bus stops
Chicago (population city: 2.7 m, metro: 9.5 m)				
2,153 bike parking spaces at 131 of the 143 CTA stations and 4,267 bike parking spaces at 50 of the 76 METRA suburban rail stations. Most (83) CTA stations provide indoor or sheltered bike parking. Usage rates of 90% and 50% for indoor and outdoor racks	All CTA and PACE buses have bike racks	Bikes permitted on CTA and METRA trains during off-peak. Bikes not permitted on escalators in stations	The routing of on-street bikeways in Chicago takes the location of transit stations into account. CTA system maps show bike parking possibilities at stations	Strengths: Ample bike parking at 131 CTA stations, of which 83 provide indoor parking. State-of-the-art Millennium bike station at downtown terminus of suburban rail line; CTA regularly collects bike rack usage data to add parking where needed
Largest bike station in the USA with indoor parking for 300 bikes, right above the terminal station for two of Chicago's suburban rail lines				Challenges: The CTA subway is old with limited ADA facilities; flights of stairs make it difficult to bring bikes on board
Toronto (population city: 2.5 m, metro: 5.5 m)				
1,771 short-term bike parking spaces and 114 bike lockers at TCC subway and GO Transit stations	55% of TTC buses and all GO Transit buses have bike racks	Bikes permitted on TTC subways, RT trains, streetcars, and buses without bike racks except during peak hours	The guiding principle of bike facility planning is to put every resident within a 5 min bike ride of the bike network	Strengths: Extensive transit system with high mode share; bike racks on most buses; bikes allowed off-peak on streetcars, subways, and suburban rail; bike parking at most transit stops

Bicycle Integration with Public Transport. Table 1 (Continued)

Bike parking at transit stops and stations	Bikes on transit		Bike routes and transit stops	Highlights: strengths and challenges
	Bike racks on buses	Bikes on trains		
New bike station at Union Station (opening spring 2009) with secure, sheltered parking for 200 bikes. Second bike station planned	All TTC buses will be equipped with bike racks by end of 2010	Bikes permitted on GO Transit trains except on trains arriving and departing from Union Station in peak direction	The Waterfront Trail which spans the Greater Toronto Area parallels the busy GO Rail Lakeshore corridor and is in close proximity to many stations	Challenges: No bikes allowed on rail transit during peak hours; lack of elevators in many stations; more bike parking and secure lockers needed at stations; no coordination of bike routes with transit stops
Washington, DC (population city: 0.6 m, metro: 5.3 m)				
1,800 bike racks and 1,300 bike lockers at Metro stations. No bike parking at bus stops, except major transit hubs with rail stations	All WMATA buses have bike racks	Bikes allowed on Metro trains during off-peak. Cyclists must use elevators between the street and the station platforms	Drafting of DC bike plan took the location of metro stops into account, particularly for the bike route network and facility recommendations	Strengths: Bike racks on all buses; bikes on Metro except during peak; lockers and racks at all stations; SmartBike short-term rentals at 8 Metro stations
Bike station for 150 bikes to open in July 2009 at Union Station		Bikes not allowed on MARC trains. VRE allows bicycles on some trains		Challenges: Restricted bike access hours on Metro; bikes restricted on VRE and MARC suburban rail
New York City (population city: 8.2 m, metro: 18.8 m)				
No dedicated bike parking at rail stations or transit terminals. Some bike parking provided by NYCDOT on sidewalks, often near transit stops. No secure bike parking of any kind in NYC	No buses with bike racks in NYC; Roughly half of NJ Transit busses have bike racks in 2010 (planned increase to 95% by 2014)	Bikes permitted on the NYC subway at all times, but only 16% of stations ADA accessible, with elevators or ramps	No explicit coordination; but the transit network in the city is so dense that most of the bike network is close to transit	Strengths: 24/7 bike access and no fees or permits on NYC subway system, most extensive in North America; big increase in bike racks and bike parking on NJ Transit
Bike parking at a third of MTA suburban train stations in NYC; bike lockers at 18 LIRR and 6 MNR stations; bike parking at 90% of NJ Transit train stations and 80% of LRT stations (a total of 2,400 bike parking spaces, with 376 bike lockers)		All suburban trains allow bikes on board during off-peak hours, but limit of 2–4 bikes per car on weekdays; NJ Transit LRT allows bikes on trains during off-peak hours with a maximum of 4–6 bikes	No coordination of bike network with transit stations and routes in suburbs; most suburban cycling facilities are recreational and do not lead to transit stops	Challenges: No bike racks on MTA buses in NYC; limited parking at MTA suburban rail stations and no bike parking at two main train stations in Manhattan; no secure bike parking; difficult to access platforms: only 16% of subway stations with elevator access

Future Directions

North American cities have been making impressive progress integrating cycling with public transport. Since 2000, the percentage of buses with bike racks has almost tripled. Bike-rail integration has also advanced. Most light rail, metro, and suburban rail systems permit bikes on their rail vehicles except during peak hours, and they increasingly provide special accommodations for cyclists such as bike hooks, racks, and rails in special areas of rail cars. Complementing provisions for bikes on transit vehicles, bike parking at transit stops has been vastly expanded over the past 10 years, with large increases in the number of racks as well as improvements in the convenience, security, and shelter of bike parking.

While cycling and public transport have considerable synergies, there are some inevitable conflicts. Surveys in some cities indicated that cyclists prefer to take their bikes with them on rail vehicles so they can use them at both ends of the trip. That can cause problems during peak hours, however, when all available capacity is needed to accommodate passengers, and there is no extra room for bikes. Taking bikes on buses is much less of a problem since bike racks are external and do not reduce passenger-carrying capacity. But even bike racks can be filled to capacity during the peak, forcing cyclists to wait for later buses.

Paradoxically, bike-and-ride can become problematic where it is most successful. Capacity problems are most likely to arise in cities with well-used public transport and high levels of cycling. That is why the European approach to bike-and-ride has favored the provision of ample, sheltered, secure bike parking at transit stops instead of accommodating bikes on transit vehicles. Similarly, in North American cities with overcrowding of rail vehicles during rush hours, the focus should probably be on providing improved bike parking at rail stations. Not only is more parking needed, but it should be of higher quality, with more sheltered and secure spaces. Major transit terminals should include multi-service bike stations, such as those in northern Europe. Similar to the concept of “complete streets,” an appropriate goal of transit

systems in North America should be to provide “complete stations,” which fully accommodate the needs of cyclists. That includes making rail platforms more accessible to cyclists, which would also improve accessibility for persons with disabilities.

Such bike-and-ride provisions cost money, but they are much cheaper than park-and-ride facilities for motorists [15]. Transit systems should shift their focus from park-and-ride to bike-and-ride, which is more cost-effective as well as more environmentally friendly. To encourage that shift, federal, state, and local government agencies should vastly expand funding for further improvements in bike-and-ride measures.

Glossary

Bioaccumulation An increase in the concentration of a substance obtained from the abiotic environment in one or more tissues of an organism. Bioaccumulation occurs within a given trophic level.

Bioconcentration An increase in the concentration of a substance from the abiotic and biotic environment in one or more tissues of an organism. Bioconcentration occurs within a given trophic level.

Biomagnification An increase in the concentration of a substance obtained from organisms at lower trophic levels by an organism at a higher trophic level.

Biosynthesis Many molecules that can be bioaccumulated or biomagnified by organisms at higher trophic levels enter the food web by being synthesized by organisms at lower trophic levels.

Food chain The simplest possible representation of producer–consumer relationships in an ecosystem.

Food web The representation of the network of producer–consumer–degrader relationships in an ecosystem.

Depuration The metabolic alteration and excretion of a substance, usually a xenobiotic molecule.

Trophic level The position in a food chain or food web occupied by a producer or consumer of food.

Definition of the Subject

In a meta-analytical review of biomagnification in marine ecosystems, Gray [1] noted that more than half of the papers purporting to study this topic were using the term incorrectly [1, p. 46]. He then went on to propose careful definitions of the ways in which xenobiotics can gain entry into organisms. As noted above in the glossary, bioaccumulation, bioconcentration, biomagnification, and biosynthesis of substances represent four different routes of entry. Bioaccumulation, bioconcentration, and biosynthesis typically account for the presence of toxic molecules in organisms at low trophic levels, with transfer of compounds from environment to organism via cell membranes in small organisms with high surface-to-volume ratios, and via gill membranes in many larger aquatic species. Accumulation of xenobiotics via biomagnification is more likely to be a phenomenon that occurs in larger animals at higher trophic levels. The suite of processes that leads to the accumulation of toxic compounds in organisms has been an important element of ecological research for decades and an issue of great practical concern relative to anthropogenic impacts on biological communities [2] as well as to the health and well-being of human populations [3].

Introduction

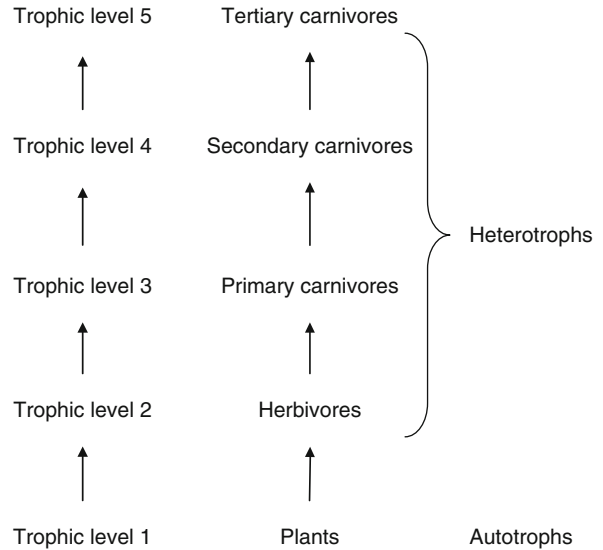

The Fundamental Ecological Context and Simple Food Chain Theory

A brief review of food chain theory will aid in understanding the processes that can lead to magnification of a non- or poorly metabolizable natural toxin or a non-biodegradable pollutant in a food chain. It is within this context of basic ecological principles that we can best view the movement, concentration, and/or transformation of such compounds that result in the degree of magnification that we find expressed in nature.

All animals need food to survive. Food may be burned (i.e., respired) to provide energy, incorporated into the animal's biomass as proteins, fats, and/or carbohydrates to provide essential structural or metabolic needs, or directed toward reproduction. Food used for these purposes takes the form of organic compounds that are collectively composed of (primarily) carbon, hydrogen, oxygen, nitrogen, phosphorus, and (secondarily) literally dozens of other elements. Organic compounds are produced from inorganic molecules such as carbon dioxide and water by a special category of organisms called autotrophs, or primary producers. Plants are the autotrophs with which most persons are familiar. They use the energy in sunlight to effect the transformation of inorganic compounds into organic matter and hence are called photoautotrophs. Less familiar to many people are the autotrophic bacteria that use chemical energy released from the mediation of oxidation–reduction reactions to synthesize organic matter from inorganic compounds. Such bacteria are referred to as chemoautotrophs. All living organisms that lack the ability to convert inorganic compounds into organic matter are called heterotrophs and depend either directly or indirectly on primary producers as a source of food.

The production of biomass by heterotrophs involves the conversion of one form of organic matter into another, a process called secondary production. Heterotrophs that eat plants are called herbivores. Heterotrophs that eat other heterotrophs are carnivores. Heterotrophs that eat herbivores are primary carnivores, and heterotrophs that eat primary carnivores are secondary carnivores. Not all heterotrophs are so easily classified. For example, some animals have rather cosmopolitan feeding habits and are called omnivores. Other heterotrophs feed primarily on nonliving organic matter (e.g., dead animals or the waste products of other heterotrophs) and are called detritivores. Regardless of whether the consumer is a herbivore, carnivore, omnivore, or detritivore, it is possible to make some broadly relevant generalizations about what happens to organic matter once it has been synthesized by autotrophs.

The successive transfers of food from prey to predator make up what is called a food chain. Each component of such a food chain is called a trophic level. Autotrophs are logically assigned to the first trophic

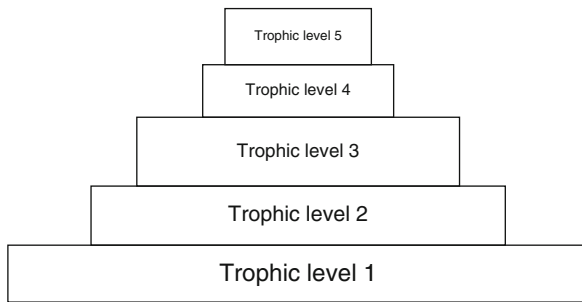

Bioaccumulation/Biomagnifications in Food Chains.

Figure 1

Diagram of a simple grazing food chain with plants as the first trophic level. Arrows indicate transfers of biomass

level in such food chains, herbivores to the second trophic level, primary carnivores to the third trophic level, and so forth (Fig. 1).

In most natural systems only a small percentage of consumed food is passed along from one trophic level to the next highest trophic level. This percentage is referred to as an ecological efficiency and is typically no more than 20%. This means that the rate at which food is ingested by a trophic level is at least five times greater than the rate at which food is passed on to the next trophic level. Most of the consumed food is either respired or excreted. Because ecological efficiencies are low, the flux of food from one trophic level to the next steadily decreases as one moves up a food chain, and the steady decrease in the flux of food to higher and higher trophic levels usually results in decreases in the biomass of organisms at successively higher trophic levels. A caveat to this last generalization is associated with the fact that organisms at successively higher trophic level tend to become progressively larger, i.e., predators tend to be larger than their prey. There are exceptions to this generalization, mainly in the cases of predators that hunt in packs or groups, such as wolves or killer whales. Because large animals generally require less food per unit biomass to sustain themselves than

Bioaccumulation/Biomagnifications in Food Chains.

Figure 2

An ecological pyramid. The decrease of biomass on successively higher trophic levels reflects the combined effects of low ecological efficiency and decreasing food requirements per unit biomass on higher trophic levels. Length of horizontal bars is proportional to biomass

small animals, the amount of biomass on successively higher trophic levels does not usually decline as much as one might expect based on the magnitude of ecological efficiencies, but in general one finds a decrease in total biomass at successively higher trophic levels. In other words, although the animals tend to be larger, there are a lot fewer of them. If the total biomass on successive trophic levels is represented by a series of horizontal bars, and if those bars are stacked on top of one another, the resultant figure has the appearance of a pyramid. That pyramid is called an ecological pyramid (Fig. 2).

The food chain consisting of plants, herbivores, and carnivores is often called the grazing food chain. Complementing the grazing food chain is another whose first trophic level consists of nonliving organic matter, i.e., dead remains of animals and plants and organic waste products excreted by heterotrophs. This nonliving organic matter is called detritus, and the associated food chain is called the detritus food chain. Simplistically, it consists of detritus, detritivores, and carnivores, and at the last step, the detritus food chain merges with the grazing food chain (Fig. 3). In a healthy ecosystem these two food chains work together to consume almost all the organic matter produced by the autotrophs. It is very important that the organic wastes produced by heterotrophs are consumed by detritivores, because such waste products are almost invariably toxic to the organisms that produce them. One food chain's waste is the other food chain's food,

Bioaccumulation/Biomagnifications in Food Chains.

Figure 3

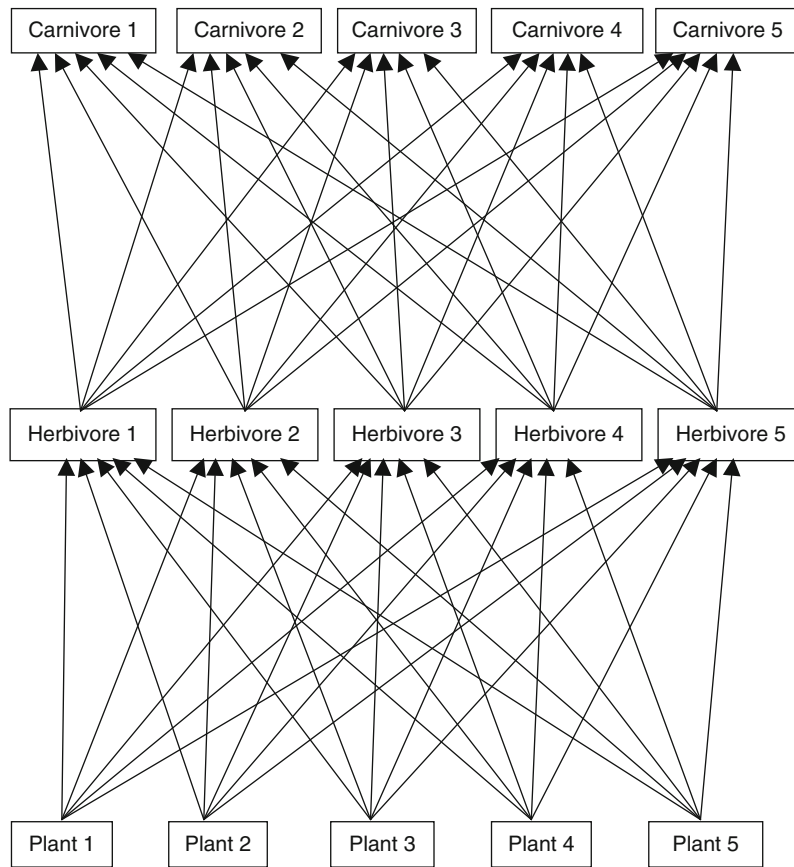

Interactions between the grazing food chain (*left*) and detritus food chain (*right*). *Solid arrows* indicate grazing, i.e., consumption of prey (food) by a predator. *Dashed arrows* indicate excretion and/or death

and of course, the carbon dioxide produced by the respiration of all heterotrophs is needed by all autotrophs for primary production. Thus the production and consumption of organic matter in a healthy community of autotrophs and heterotrophs is characterized by a great deal of recycling.

A variation on the concept of food chains is the depiction of feeding relationships as food webs (Fig. 4), in which the feeding relationships of (typically) individual species are represented in a two-dimensional diagram. Since a given predator may feed on more than one and perhaps many different prey species, such a diagram tends to have a very complex appearance and has the general characteristics of a web as opposed to a chain. However, careful examination of the feeding relationships depicted by a food web often reveals a pattern consistent with the food chain model. And the principles that govern the fate of consumed food apply regardless of whether feeding relationships are depicted by a food web or food chain. For purposes of this chapter, we will rely on the food chain model to rationalize/explain issues that arise from biomagnification, and we will use the interactions between the grazing and detritus food chains to illustrate how recycling can lead to results that are somewhat counterintuitive from the standpoint of simple food chain theory.

Food Chain Magnification Principles

Given the rather low ecological efficiencies that characterize most food chains, it is not hard to imagine how

Bioaccumulation/Biomagnifications in Food Chains. Figure 4

Feeding relationships in a hypothetical food chain in which each of five plant species is grazed by each of five herbivore species, which in turn is grazed by each of five carnivore species. The arrows depicting the feeding relationships have the appearance of a web, and such diagrams are characterized as food webs. In this particular case, however, the flow of organic matter could be just as well represented by a simple food chain consisting of plants, herbivores, and carnivores, as on the left side of [Fig. 3](#)

the concentration of a relatively refractory substance might be magnified from one trophic level to the next. Assume for the sake of argument that xenobiotic substance X cannot be respired. This would be the case, for example, if X happened to be a metal such as lead or cadmium. Assume further that for whatever reason X is not effectively excreted. This happens to be the case for methylmercury. For humans, about 95% of ingested methylmercury is, at least initially, retained by the body. Assume as a worst case scenario that X is neither respired nor excreted and instead is retained with 100% efficiency in the body of the consumer organism. If the ecological efficiency in the food chain is 20%, then the concentration of X in the food consumed by one

trophic level will be magnified by a factor of five in the food consumed by the next trophic level. In a grazing food chain consisting of five trophic levels, beginning with plants and ending with tertiary carnivores, the concentration of X in the tertiary carnivores should be $5^4 = 625$ times higher than the concentration of X in the plants. The fact that the concentrations of ostensibly refractory xenobiotics are sometimes found to be very high in the tissues of top-level carnivores has naturally led to speculation that exactly this sort of mechanism, i.e., biomagnification or food chain magnification, is responsible.

To illustrate this point, [Table 1](#) shows concentrations of residues of the pesticide DDT in the water and

Bioaccumulation/Biomagnifications in Food Chains.**Table 1** DDT residues (DDT + DDD + DDE) in water and organisms taken from a Long Island Salt Marsh [2]

Organism	DDT residues (ppm)
Water	0.00005
Plankton	0.04
Silverside minnow	0.23
Sheephead minnow	0.94
Pickarel (predatory fish)	1.33
Needlefish (predatory fish)	2.07
Heron (feeds on small animals)	3.57
Tern (feeds on small animals)	3.91
Herring gull (scavenger)	6.00
Fish hawk (osprey) egg	13.8
Merganser (fish-eating duck)	22.8
Cormorant (feeds on larger fish)	26.4

in various organisms taken from a Long Island, New York, salt marsh [2]. The data illustrate how very low concentrations of toxic substances in the water and/or in organisms at low trophic levels may increase dramatically through the food chain. The residue concentrations increase steadily from the plankton to small fish, to larger and larger fish, and finally to fish-eating birds. The total concentration factor from plankton to fish-eating birds is about 600, which suggests that the concentration factor between successive trophic levels may be about a factor of 5 (see above).

Agreement between theory and observation does not, however, prove that the theory is correct. There are other processes that can affect the concentrations of xenobiotics in the tissues of animals. Fish, for example, must constantly pump water over their gills to breathe. It is certainly possible that direct transfers of xenobiotics from water to fish may occur through the gills. This exchange may lead to high concentrations in the tissues of the fish by a mechanism (bioaccumulation) that has nothing to do with food chains. In a classic study, Hamelink [4] demonstrated that the concentrations of DDT residues in the tissues of fish in experimental ecosystems were unaffected by whether the

DDT residues entered the fish directly from the water or through a combination of entry via the water and food chain. The implication was that the food chain route was, at least in that case, insignificant compared to direct uptake from the water. And in contrast to the Woodwell et al. [2] results, Harvey et al. [5] found no evidence for biomagnifications of DDT residues in Atlantic Ocean food chains. In fact, the DDT residues were highest in the plankton and were ten times lower in flying fish, which feed largely on plankton. During the 1960s, when DDT was being used extensively in the United States and many other countries, sharks were found to contain high concentrations of DDT residues, but barracuda, which are also top-level carnivores, contained about 100 times lower concentrations than sharks [6]. The implication of these and other studies is that high concentrations of xenobiotics in top-level carnivores is not *prima facie* evidence of biomagnification, and among organisms occupying ostensibly similar positions in a food chain xenobiotic concentrations may vary widely as a result of differences in the extent to which organisms bioconcentrate xenobiotics directly from the environment.

An additional concern is the interaction between the grazing and detritus food chains, which is overlooked in the simple paradigm of food chain magnification. The consequences of this interaction are illustrated by a study of Isaacs [7, 8] that concerned concentrations of cesium (Cs) and potassium (K) in the muscle tissues of fish from the Salton Sea and Gulf of California. Briefly, the Cs/K ratio had been found to increase by a factor of three between successive trophic levels in the grazing food chain of the Salton Sea. However, the Cs/K ratios in similar fish from the Gulf of California were independent of the trophic level of the fish and about 16 times higher than the Cs/K ratios in the algae. Isaacs [7, 8] developed a mathematically complex unstructured food web to account for these differences. Laws [9] showed that the same results could be explained by taking into account the recycling that occurs between the grazing and detritus food chains (Fig. 3).

The conclusion is that a great many factors can influence the concentrations of xenobiotics in the tissues of plants and animals. Biomagnification, or food chain magnification, is one of those factors. But interactions between the grazing and detritus food chain can

lead to results that are not predicted when the detritus food chain is ignored, and bioaccumulation in at least some cases can be more important than biomagnification in determining xenobiotic concentrations within organisms. With this introduction, we consider in detail two human health issues potentially impacted by biomagnifications, ciguatera fish poisoning, and methylmercury intoxication.

Ciguatera Fish Poisoning

History

At the 14th Conference of the International Society for the Study of Harmful Algae, Fraga [10] described what is believed to have been the first reported case of ciguatera fish poisoning, an incident that occurred in 1525 in the Gulf of Guinea. An entry in an old manuscript described a case that happened in a Spanish fleet led by Andrés de Urdaneta. The fleet was en route to the Pacific through the Strait of Magellan. The journal entry translates as follows:

- On this island, a very beautiful fish called barracuda was caught by the flagship, and the Captain General invited some of the captains and officers of the King. All who ate the barracuda fell ill from diarrhea and were unconscious, so we thought they had died; however our Creator wanted everyone to be saved.

The fish responsible for this incident, a barracuda (top-level carnivore), is a fish not infrequently implicated in ciguatera fish poisoning. This case was subsequently reported by other early chroniclers, demonstrating how important the incident was.

Five years later, Peter Martyr, the early historian of the West Indies, wrote that when people eat certain fish, they “are attacked by divers strange maladies” [11]. Interestingly, Martyr ascribed this poisoning to movement of a toxin through what we would now call a food chain, from an origin in a plant, to fish, to humans.

In 1601, Pedro Fernández de Quirós, a Portuguese navigator in the service of Spain, reported that his entire crew was poisoned after eating “pargo,” fish that may well have been snapper or grouper, that they caught while anchored off the island of Espiritu Santo in what is now Vanuatu [12]. The most descriptive of the early accounts of ciguatera, however, comes from the famous British explorer Captain James Cook. In his

journal entry for Sunday the 24th of July, 1774 [13], Cook wrote:

- “The Night before we came out of Port two Red fish about the size of large Bream and not unlike them were caught with hook and line of which most of the officers and some of the petty officers dined the next day. In the evening everyone who had eat of these fish were seiz’d with violant pains in the head and Limbs, so as to be unable to stand, together with a kind of Scorching heat all over the Skin, there remained no doubt but that it was occasioned by the fish being of a Poisoness nature and communicated its bad effects to everyone who had the ill luck to eat of it even to the Dogs and Hogs, one of the latter died in about Sixteen hours after and a young dog soon after shared the same fate. These must be the same sort of fish as Quiros mentions under the name of *Pargos*, which Poisoned the Crews of his Ships, so that it was some time before they recovered. We had reason to be thankfull in not having caught more of them for if we had, we should have been in the Same Situation.”

Another of Cook’s officers identified the suspect fish as “Groopers”; it is likely that the fish Cook’s men ate on the 23rd of July, 1774 were either snapper or grouper.

Nature and Extent of the Problem

Ciguatera fish poisoning (CFP) is a worldwide health problem that represents an example of biomagnification of a naturally produced marine toxin. CFP is a non-bacterial, food-borne disease associated with the consumption of seafood that originates from coral reef environments in tropical and subtropical regions of the world. Humans contract the disease by consuming reef fish that have accumulated ciguatoxins as a result of feeding in coral reef habitats. Public health institutions throughout the world rank CFP as the most common food-borne disease related to the consumption of marine finfish [14].

In the introduction to this entry, the distribution of concentrations of DDT residues in organisms representing various trophic levels in a Long Island salt marsh were shown to be positively correlated with trophic level. The biological world frequently does not present itself as being so orderly. The relationships

between concentrations of naturally occurring marine toxins and trophic levels are considerably more difficult to discern given the variability caused by the complexity of marine food web interactions [7–9]. The next few paragraphs will explore the scope of the CFP problem, including the organisms responsible for toxin synthesis, natural pathways of the toxin through food webs, and biological and clinical evidence related to ciguatera fish poisoning.

CFP represents an example of biomagnification of a marine toxin that is produced by natural processes and, while presenting substantial difficulties for quantification and study, affects humans like no other toxin from the marine realm. Early work by Randall [14], Banner et al. [15, 16], and Banner and Helfrich [17] indicated that ciguatoxin (CTX) was derived from food consumed by fish and showed that toxicity could be transferred to non-toxic fish via consumption of toxic fish. These contributions evolved into the food web concept for CFP that is the paradigm to this day.

CFP has affected coastal populations and travelers in tropical and subtropical regions throughout the world for centuries. From old ship logs noted above, through WWII chronicles when CFP was a serious problem for military troops stationed in Pacific island locales, to the present day, CFP has been a serious public health problem. Currently, there are at least 50,000 reported cases of CFP cases per year [18, 19], but due to the high degree of misdiagnosis and underreporting, it is estimated that the actual frequency of CFP cases is closer to 500,000 per year [20]. It is estimated that >50% of the populations of small islands in the Caribbean and South Pacific have suffered from CFP. Interested readers are directed to reviews by Lewis [21], Lange [22, 23], and Fleming et al. [24] for additional details on the degree of CFP incidence in populations inhabiting various locales.

Symptomology

CFP produces gastrointestinal, neurological, and cardiovascular symptoms. These normally develop within 12–24 h of eating contaminated fish. Gastrointestinal effects may disappear within 4 days. Normally gastrointestinal symptoms are followed by neurological symptoms. The gastrointestinal symptoms commonly

include diarrhea, abdominal pain, nausea, and vomiting. The neurological symptoms that ensue may include numbness and tingling in the appendages (e.g., hands and feet), dizziness, altered hot/cold perception, muscle aches, low heart rates, and low blood pressure. The key pathognomonic symptom is the neurological malady of reversal of hot/cold sensation, i.e., hot feels cold and cold feels hot. Such conditions are caused by the disruption of the “vernacular” that neurons use to communicate with one another, i.e., the ion signals involving sodium and potassium. The suite of symptoms associated with CFP is caused by ciguatoxin’s ability to increase Na^+ permeability through the Na^+ channels of excitable cells (e.g., neurons and muscle cells) that are open at normal resting membrane potentials. This enhanced excitability of the membrane in turn affects $\text{Na}^+ - \text{Ca}^{+2}$ exchange and mobilizes intracellular Ca^{+2} . The primary receptor site of the CTX action is the 5th domain of the Na^+ channel, where it causes increased sodium ion permeability and depolarization of the resting membrane. The prolonged depolarization of nerve cells is understood to cause the suite of sensory discomfort symptoms associated with CFP [25]. CFP symptoms may persist in some form for weeks, months, or even years [26]. Generally, the gastrointestinal symptoms and general weakness last about 1 week, but the neurosensory manifestations (e.g., muscle aches, tingling extremities, and thermal reversals) commonly represent the most prolonged discomfort. It is interesting that CFP intoxication does not confer any immunity in its victims; on the contrary, CFP intoxication results in a heightened sensitivity to ciguatoxin in the victim.

Fortunately, death from CFP is rare (i.e., <0.1%), and when it has occurred it was generally the result of respiratory failure due to cardiovascular shock induced by severe dehydration. Death is frequently associated with the consumption of internal organs of the fish (e.g., liver, brains, gonads, viscera, etc.) in addition to the muscle tissue that is usually consumed. Given the exceptional potency of ciguatoxin (CTX), the low death rate merits some discussion. The two most plausible explanations for the low frequency of fatalities associated with CFP are (a) the large size differential between the “average” human and the average serving of CTX-contaminated fish, and (b) the likelihood that ciguatoxin cannot biomagnify indefinitely in nature.

To understand the consumer meal size differential, consider a person weighing between 125 and 200 lbs who consumes an 8-oz portion of contaminated fish; that serving represents 0.25–0.4% of the biomass of the consumer. Since reef organisms do not attain a size of 125–200 lbs, the final “dilution” of the toxin at the point of the human is large with respect to the dilutions that are experienced at various junctures within the marine reef ecosystem. The second explanation is related to the effects that the CTX toxin has on the various animals within the marine reef ecosystem. The ingestion of the ciguatoxin via the consumption of a contaminated organism (lower on the trophic structure) has been shown to cause behavioral changes in animals [27]. If, as has been suggested, such impaired behaviors may make those infected animals more susceptible to death, it would present a natural truncation of the CTX magnification food chain. This, together with the roughly 300-fold dilution factor at the serving-human juncture, may be the reason that humans rarely ingest levels of CTX of sufficient magnitude to cause a fatality.

Environmental and Biological Controls

The distribution of ciguatoxic fish is frequently stated as being within the 35°N and 35°S latitudinal band. Patterns of CFP incidence are well known for the Pacific, Indian, and Atlantic oceans, as well as the Caribbean and Mediterranean Seas [28]. Nonetheless, recent scientific inquiries have suggested an even more expansive geographic scale for ciguatera incidence [29]. It has also been suggested that the latitudinal range for CFP is expanding as a consequence of warming sea surface temperatures associated with climate changes [30]. The relevance of the expanding latitudinal range lies in the fact that the inclusion of higher latitude regions will include some areas with high population densities, which suggests the potential for increased incidence rates. Several informative reviews on CFP may be found in Lehane and Lewis [31], Bienfang et al. [31], Dickey [26, 27], Dickey and Plakas [32], and references cited therein.

In contrast to the orderly increases of DDT residue concentrations in organisms at various trophic levels presented in the introduction to this entry, the biomagnification scenario for CTX is complex. The

difference for CTX is nested in the fact that the concentrations and potency of this naturally produced marine toxin are modified through the complexity of marine food web interactions. Reasons for the apparent complexity of CTX biomagnification include the following:

1. Precursors of the CTX toxin, gambiertoxins, are produced by a variety of dinoflagellates belonging to the genus *Gambierdiscus*. These species vary significantly in terms of their tendency to produce toxins and the potency of the toxin they produce.
2. Metabolites of gambiertoxins, the CTX toxins themselves, appear in a variety of chemical forms (i.e., congeners). Additionally, the toxins are potent at very low dosages and are odorless, tasteless, and highly resistant to destruction/detoxification.
3. Spatial and temporal environmental variability appear to influence the production and flux of CTX into fish populations.
4. The complexity of the marine food web leading to the distribution of CTX among fishes harvested by man presents multiple vectors that may lead to human maladies in a given situation.
5. Humans display variable sensitivities to and symptomologies from CTX intoxication.

A genus of single-celled algae called *Gambierdiscus* (division Phaeophyta, commonly known as dinoflagellates) produces the gambiertoxins that are the natural precursors of CTX. This genus of dinoflagellates does not form conspicuous blooms that color the water like some other dinoflagellates that are known to produce “red tide” aggregations. The *Gambierdiscus* species normally grow epiphytically on various macroalgae in coral reef ecosystems. The need of these sessile, benthic macroalgae for sufficient sunlight for photosynthesis accounts for the limitation of ciguatera to organisms that inhabit and derive most of their nutrition from the relatively shallow coral reef environments found in warm, tropical areas. *Gambierdiscus toxicus* was originally designated as a new genus and species by Adachi and Fukuyo [28]. Since then, at least ten new species have been added to this genus [33–36]. It has long been suspected that the various *Gambierdiscus* species differ significantly in their degrees of toxin production [33, 34, 37–41]. These dinoflagellates are consumed by herbivorous fish,

beginning the process of bioaccumulation and biomagnification through the reef food web. The herbivores are consumed by carnivores, which in turn are consumed by humans.

The Toxin

CTX is a polar, lipid-soluble, highly oxygenated polyether molecule; it consists of 13–14 rings that are fused by ether linkages into a ladder-like structure [42–48]. The seminal toxins that are produced by cells of *Gambierdiscus* are frequently designated as gambiertoxins. These are less polar than the ciguatoxins isolated from fish. These less polar precursors are considerably less potent than the CTX molecule found in high trophic level carnivores. Because the different *Gambierdiscus* species/strains often co-occur at various relative abundances and can vary with respect to their individual toxicities, the resulting variability of toxin flux into the food web has confounded monitoring efforts. Ciguatoxins are piscine metabolites of the gambiertoxins that are assimilated and metabolized through multiple trophic levels of the marine food web. Ciguatoxins in fish may comprise an assemblage of principal ciguatoxins and numerous closely related structural isomers and congeners. Toxins isolated from different regions and/or organisms have been shown to exist in a number of forms that have different molecular weights, chemical structures, and toxicities [42, 48–53]. The recognition of these congeners necessitated new nomenclature, and in the more recent literature an I, P, or C prefix refers to the ocean of origin (i.e., Indian, Pacific, or Caribbean), and a number following refers to a specific congener/form of CTX. Thus, P-CTX-1 would refer to CTX congener 1 isolated from the Pacific Ocean. There are currently understood to be 29 congeners of P-CTX, and 12 of C-CTX. More robust analytical methods have revealed important new details regarding the chemical structure of CTX and its congeners.

Ciguatoxin is one of the most potent natural toxins known; the intake of picogram (i.e., 10^{-12} g) amounts of toxin will cause clinical symptomologies in humans. Such potency at minuscule concentrations has presented imposing challenges to the analytical techniques that may be applied for measurement of CTX in

fish tissues. The need for sophisticated chemistry presents exceptional challenges for the quantitative analysis of CTX at concentrations that produce clinical symptomologies in humans. The equipment required for analyses of complex organic compounds such as CTX is expensive to purchase and maintain, and requires highly talented analytical chemists to operate. This requirement for CTX detection has been addressed by a variety of approaches over the decades. Early work involved a number of non-ciguatera-specific bioassay procedures using mouse neuroblastoma cells and various invertebrates and vertebrates; these were followed by radioimmunoassay, enzyme immunoassay, and immunobead assays [54]. More recent analytical developments have focused on chromatographic methods involving high performance liquid chromatography (HPLC) combined with mass spectrometry (MS) [27, 55–57]. These robust analytical techniques are very expensive and require sophisticated infrastructural support. An important consequence of this range in analytical procedures used for CTX analyses has been a lack of uniformity, sensitivity, and specificity of analyses used by investigators working in various regions over the years.

Variability of Incidence

Within areas that are known to be prone to CFP incidence, the distribution of toxic fish can be highly variable on small scales both temporally and spatially. This is thought to be due to ecological factors that influence the degree of dietary intake of CTX by fishes, the degree of CTX biotransformation that may occur, the age/growth rates of the fish, and rates of CTX excretion (which are normally slow, and on the order of months). As a consequence, ciguatoxicity has been found to vary seasonally, from species to species, and from location to location within fairly proximate areas. A species of fish in one area may be relatively free of ciguatera but found in close proximity to an area where that same species is highly ciguatoxic. Such heterogeneous distributions of ciguatoxic fish have been described for numerous locations throughout the Caribbean Sea, Indian, and Pacific Oceans, and have been attributed variously to the combined forces of the territorial nature of carnivorous reef fish, differences in the abundance and/or

toxicity of *Gambierdiscus* spp., or variations in feeding patterns between locations.

An example was described by Lewis [58] for the mid-Pacific location of Kiribati, where southern (Tarawa) and western (Maraki) reefs were known for high CFP incidence, but not other reefs in the vicinity. Dierking [59] showed similar spatial heterogeneity in the distribution of ciguatoxic *Cephalopholis argus* throughout coastal areas on the islands of Oahu and Hawaii, Hawaii. The biomass of *C. argus*, introduced to Hawaii from French Polynesia in the 1950s, now surpasses the biomass of all other reef predators combined, and is one of the principal species associated with CFP in this area. Dierking's [59] findings showed substantial (8% versus 24%) differences in the prevalence of toxic *C. argus* between the islands of Oahu and Hawaii, large variations in toxicity within sites, no clear patterns between sites on either island, and very weak correlations of toxicity and fish size. Similar lack of correlation of either incidence or severity of ciguatoxicity with fish size, and high degrees of spatial heterogeneity in the incidence of ciguatoxicity in *C. argus* has been shown by Bienfang and DeFelice (unpublished data; www.fish4science.com).

The complexity of the marine food web leading to ciguatoxic fishes that are consumed by man has challenged marine scientists who have studied the ecosystem looking for vectors that contribute to this human malady. There is evidence that individual *Gambierdiscus* strains differ considerably in their inherent ciguatoxin production capabilities [34, 39, 56, 60]. Laboratory studies have suggested that individual *Gambierdiscus* strains are adapted to particular environmental regimes (e.g., different relationships between light intensity and growth rate, toxicity and light intensity, temperature, and/or salinity [60–63]. Changes in the dietary intake of ciguatoxins within food webs leading to fish have been described as being influenced by a variety of stochastic changes in predator–prey relationships within areas. Despite a low correlation between changes in ciguatera incidence rates and catastrophic events, it has also been repeatedly speculated that anthropogenic disruptions (e.g., shipwrecks, dredging) and/or natural environmental disturbances (e.g., hurricanes, cyclones, coastal inundations) may lead to the availability of new

surfaces for colonization by macrophytic algae and/or the associated epiphytic *Gambierdiscus*.

The apparent differences in sensitivity of individuals to ciguatoxic fish and/or associated variability in the severity of symptomologies from CTX intoxication among afflicted victims, together with a high (e.g., 90%) degree of underreporting has also confounded elucidation of processes associated with ciguatera prevalence. Although symptomologies that are consistent with an interference with sodium channel activity are characteristically associated with CTX [27, 57], other biochemical aberrations have also been implicated [56, 64, 65]. Also, it is relatively infrequent that remains of a meal that apparently caused CFP in a human have been available for credible analysis of ciguatoxin. When possible, analyses have shown ciguatoxicity in humans at concentrations in fish ranging from 0.1 to greater than 1 part per billion P-CTX-1.

Evidence of Biomagnification

Despite all these vagaries in the databases associated with CFP, the role of biomagnifications is suggested by the fact that high-level carnivores are by far the fish most frequently associated with the presence of CTX. The data pertaining to CFP incidence in fishes comes from both clinical records and sampling studies that broadly examined various reef species for ciguatoxicity irrespective of associated incidence of reported symptomologies by humans. Not surprisingly, data from the clinical records have had considerably more influence on our perspective regarding the piscivorous vectors leading to CFP. This comes from the standpoints of both their numerical abundance and their role in initiating the broad-scale studies of ciguatoxicity across fish species inhabiting reef ecosystems in various geographic locations. CTX is capable of bioaccumulating through the food chain through herbivorous and carnivorous (i.e., predatory) reef fish.

The fish most commonly involved in CFP incidents within various geographic locations have been listed/prioritized in several summaries [54–56, 59, 66–71]. Such listings show that the fish species that are most commonly implicated with ciguatoxicosis are primarily carnivorous. The prominent carnivorous taxa include the barracudas (*Sphyraena* spp.), groupers (*Epinephelus*

spp.), jacks (*Caranx* spp.), snappers (*Lutjanus* spp.), mackerels (*Scomberomorus* spp., especially the Spanish mackerel), kingfish (*Seriola* spp.), and moray eels (e.g., *Gymnothorax* spp.).

Not all fish implicated in CFP are carnivores. Non-carnivorous taxa include the detritivorous/omnivorous surgeonfish (*Ctenochaetus* spp.), parrotfish (*Scarus* spp.), and wrasses (e.g., *Cheilinus* spp.). In the Pacific, the detritivorous grazer, *Ctenochaetus striatus* (a surgeonfish), is frequently ciguatoxic and is thought to be a key vector amplifying CTX up the food chain. High levels of CTX and other *Gambierdiscus*-associated toxins in biodetritus are believed to account for the frequency of ciguatoxicity in *C. striatus*, and occasionally, mullets (e.g., *Mugil* spp.) because both have detritivorous grazing behaviors [72]. The mouthparts of the *C. striatus* are especially well adapted for feeding on phytodetritus and certain filamentous macroalgae known to commonly be host to the epiphytic *Gambierdiscus* spp. Surgeonfish and parrotfish tend to be dominant families by weight on many coral reefs, and among the most common prey of larger piscivores. Interestingly, carnivorous species that are grown in tropical aquaculture settings have been shown not to display ciguatoxicity, despite the presence of *Gambierdiscus* spp. growing on the confining vessels used in the culture process [73]. This lack of ciguatoxicity due to bioaccumulation has been attributed to the fact that the majority of the nutrition of such cultured carnivores is provided through the provision of prepared feeds supplied to the culture systems, rather than (normal) grazing upon a heterogeneous suite of natural feedstuffs.

The perceived variety in CFP symptomologies between fishes from the Caribbean and Pacific has variously been attributed to differences in the gambiertoxins produced by different predominant *Gambierdiscus* species in these locales, and/or the portions of the fish traditionally consumed. Helfrich et al. [74] estimated that the relative toxicity of fish liver tissue was 50 times greater than that in the muscle tissue. Vernoux et al. [75] similarly showed that the relative toxicity of the liver and viscera tissues (e.g., brain, gonads, heart) was considerably higher than that of the muscle tissue. This has been attributed to the preferential sequestering of the lipid-soluble CTX

molecule in the most lipid-rich portions of the fish. Such differences in the portions of a given fish species that are actually ingested by an assortment of populations from various geographic and/or ethnic backgrounds confound the analysis of the degree of trophic-level influence independent from other, potentially aliasing factors.

The high trophic level barracuda (*Sphyræna* spp.) has been shown to accumulate and retain CTX in its muscle tissue for extended periods of time, and toxicity was shown to be inducible. Banner et al. [16] and Helfrich and Banner [76] fed *Lutjanus* sp. ciguatoxic fish and showed the induction of toxicity within 6 months, and the subsequent retention of potency for 30 months following the cessation of feeding ciguatoxic fish. There exist chemistry results suggesting that CTX precursors from dinoflagellates may be oxidatively biotransformed to numerous congeners within herbivorous and carnivorous fish [53]. Biomagnification effects also appear to be evidenced in the human symptomologies caused by the consumption of herbivorous versus carnivorous fish. Bagnis and Legrand [77] and Kodama and Hokama [78] reported that the ingestion of ciguateric herbivorous fish caused mostly gastrological and mild neurological symptoms, while the consumption of carnivorous fish was associated with a broader and more severe suite of symptoms. This was attributed to differences in the ciguatoxin congeners produced by various (predominant) *Gambierdiscus* species in these locales, inevitably leading to an assortment of compounds present in fish representing a range of trophic positions.

There are many obstacles to a clearer definition of the prevalence of ciguatoxic fish and/or the distribution of ciguatoxic fish within a species or trophic structure. These impediments include vagary due to the temporally sporadic and spatially patchy distribution of both the causative agent (*Gambierdiscus* spp.) and the feeding patterns of the herbivorous and carnivorous fish species that lead to human CFP intoxications. The primary evidence for the biomagnification of CTX up the trophic structure is found in both the higher frequencies of CTX incidence in carnivores and the severity of symptomologies that have been observed in association with human consumption of carnivorous fish versus herbivorous fish.

Methylmercury

Hg: Sources and Cycling

Mercury (Hg) is a heavy metal. In nature, it exists in three chemical forms. These include the pure, elemental form (i.e., the form that in times past was used in thermometers), inorganic mercury compounds (i.e., mercury salts), and organic mercury (mercury incorporated into organic molecules). If you are old enough to remember gasoline at less than a dollar per gallon, you probably remember mercury as that strange, heavy, silver liquid that you rolled around on the counter top or in your hand. You are also likely to associate it with thermometers. If you are younger than that, you are most likely to think of mercury as a pollutant.

Methylmercury in the form of compounds such as methyl mercuric chloride, CH_3HgCl , and dimethyl mercury, $(\text{CH}_3)_2\text{Hg}$, is the most common form of mercury in the food people eat and is primarily responsible for the adverse human health effects attributed to mercury. Methylmercury is highly toxic and is readily bioaccumulated and biomagnified in freshwater invertebrates, marine invertebrates, freshwater fish, marine fish, marine mammals, and terrestrial mammals (including humans). The majority of methylmercury in freshwater and marine aquatic systems is derived from the conversion of other forms of mercury; rarely is methylmercury directly discharged into aquatic systems [79].

Mercury distribution within the environment (i.e., atmospheric, terrestrial, and aquatic) is controlled by complex biogeochemical cycles and ecological interactions. Sources of environmental mercury input may be divided into natural and anthropogenic categories: The relative magnitude of these categories is roughly equal [80, 81].

Natural contributions include such sources as volcanic eruptions, forest fires, weathering of mercury-bearing rocks/geological deposits, and aquatic volatilization [82]. Volcanic eruptions are enormous contributors on a per-event basis, but rare in terms of event frequency. Forest fires are intermediate contributors on a per-event basis but represent a higher frequency of event than volcanic eruptions. The weathering of geological deposits represents a slow but continuous contributory process. Volatilization,

sometimes referred to as recycling, occurs when mercury is released back into the atmosphere as a gas from freshwater and marine aquatic systems. An example would be the breakdown of methyl mercury by sunlight [83].

The various natural inputs of mercury to the environment enter primarily to the atmosphere. Once in the atmosphere, mercury can circulate for years, during which time it becomes widely distributed throughout the planet [84]. Mercury deposition from the atmosphere to the land or water can occur in either aqueous or dry forms. Aqueous forms include rain, snow, sleet, hail, and fog. Dry forms include gas or particulates. The principal atmospheric contributor is rain. Atmospheric deposition may enter aquatic systems directly as rainfall, or indirectly as a result of either surface runoff from terrestrial systems (i.e., in streams and/or rivers) or percolation followed by subsequent input from groundwater [83].

The anthropogenic sources of mercury are those inputs that result from the activities of humans. These anthropogenic inputs can be divided into four categories: (1) area sources, (2) combustion processes, (3) manufacturing activities associated with metals, alkali, and cement, and (4) other industrial processes. Landfills, dental preparations (e.g., mercury fillings), and laboratory operations are examples of area sources. Examples of combustion processes include coal-burning power plants and/or the burning of any other fossil fuel, medical waste incineration, and municipal waste combustion. Other industrial processes include such things as discharges from mining operations, hydroelectric plants, and pulp and paper production.

The primary anthropogenic contributors of mercury to the environment include coal combustion, chlor-alkali production (i.e., production of chlorine and sodium hydroxide), waste incineration, and metal processing. The relative proportions of mercury emissions to the atmosphere, exclusive of the burning of biomass, are illustrated by data from the year 2000 [80]. Relative proportions of mercury emissions to the atmosphere were 65% from stationary combustion, 11% from gold production [85], 6.8% from non-ferrous metal production, 6.4% from cement production, 3.0% from waste disposal (municipal and hazardous waste, crematoria and sewage sludge

incineration), 1.4% from pig iron and steel production, 1.1% from mercury production (mainly for batteries), and 2.0% from other sources.

Methylmercury is the most toxic form of mercury. It is formed by the methylation of inorganic mercury [79]; methylation means a single carbon methyl group (i.e., CH_3^-) is transferred from an organic compound and becomes bound to an inorganic mercury ion (i.e., Hg^{2+}) [86]. Methylation can occur by either biotic or abiotic means, with the former being the principal mechanism [83]. Examples of such biotic methylation include catalysis by microorganisms that live in freshwater systems (lakes, rivers, wetlands, sediments, soils) and/or the open ocean [87]. To a lesser extent, mercury methylation sometimes can occur via natural processes such as photochemical reactions; these are termed “abiotic processes” [83]. Methylmercury rather than inorganic mercury is bioconcentrated because organisms at various levels in the food chain retain it more efficiently. Inorganic mercury enters bacteria via a specialized transport protein that takes the mercury across the lipid membrane of the bacterial cell wall; this uptake is a key first step in both the methylation and bioaccumulation of mercury [83]. In contrast to other forms of mercury, which are not reactive and thus diffuse out of the cell as fast as they enter, methylmercury is reactive. This is the key to its accumulation in bacterioplankton and phytoplankton, which initiates the bioaccumulation process throughout the feedweb.

Bacteria that contain methylmercury may be passed to higher trophic levels when they are consumed by bacterivores or particle feeders. Alternatively, the bacteria may excrete the methylmercury into the water, where it can become adsorbed to planktonic particles and/or nonliving particulate material suspended in ocean systems. Similarly, methylmercury can be adsorbed by marsh grasses or other microscopic or macroscopic aquatic plants in freshwater systems. Through this mechanism mercury can enter the foodweb when these plants are subsequently consumed by herbivores or detritivores.

Methylmercury may be biomagnified in both marine and freshwater aquatic food webs, i.e., the methylmercury concentrations (i.e., grams mercury per gram biomass) increase at successive trophic levels. Methylmercury concentrations have been shown to generally increase as mercury is passed from

invertebrates and/or herbivorous fish to piscivorous fish, and ultimately humans [88]. As was illustrated for DDT residues above, methylmercury concentrations in marine apex predators can reach a level orders of magnitude higher than the concentration present in the water. The extent of concentration at the highest trophic level is influenced by the number of trophic levels in the system [88]. Methylmercury has a half-life of approximately 2 years in aquatic organisms. Such a prolonged residence time results in its bioaccumulation within aquatic food chains [79]. By contrast, methylmercury has a half-life of about 50 days in human blood [89].

Mercury Poisoning: Human Symptomologies and Historical Examples

Mercury is a neurotoxin. Many adverse health effects are associated with its accumulation in the human body. These effects vary depending on the amount of mercury one is exposed to, time of exposure, the mode of entry to the human body, the chemical form of the mercury, and the age of the subject.

Methylmercury is easily absorbed through the gastrointestinal tract when ingested. Mercury readily binds to proteins and therefore is not easily eliminated. Unlike essential metals such as iron, copper, or zinc, the human body does not require mercury for any purpose. The toxicity of mercury is closely related to its tendency to bind to sulfur and selenium, and in particular to amino acids that contain these elements: cysteine and methionine in the case of sulfur, and selenocysteine, selenohomocysteine, and selenomethionine in the case of selenium. Methylmercury, for example, can form a complex with cysteine that resembles methionine. In this methionine-resembling complex, methylmercury may be transported freely throughout the body, including across the placenta and blood–brain barrier, as well as through breast milk.

The uptake of mercury by humans generally occurs via two modes. One is inhalation. Metallic mercury (Hg^0) may be present in ambient air, particularly downwind from coal-burning power plants. Alternatively, mercury may be released from dental amalgams, and as methylmercury (CH_3Hg^+) from the consumption of foods such as fish. The human body is better adapted for mitigating the potential toxic effects of

vaporous mercury, so health effects from this source are relatively rare and are generally limited to cases where the victim in question is in close and prolonged proximity to a source of elevated mercury in the atmosphere. Methylmercury, on the other hand, is the most biochemically active form of mercury. It affects the central nervous system and can cause irreversible damage to areas of the brain. Damage to the nervous system is the most prevalent of methylmercury effects on humans, but methylmercury exposure can also harm the lungs and kidneys [90] and has been linked to increased risk of cardiovascular disease [91–93]. The first symptom of methylmercury exposure in adults is generally paresthesia, a sensation of tingling on the skin. This usually manifests itself as numbness and tingling in the extremities, though paresthesia may also occur in other parts of the body as well. This is normally the first manifestation of damage to the central nervous system [94]. In cases where elevated, more extreme doses of methylmercury poisoning occur, the initial paresthesia symptoms may be followed by ataxia and generalized weakness. Ataxia refers to a wobbliness, unsteadiness, and general lack of coordination. It reflects dysfunctionality in the cerebellum and is manifested by the brain's failure to regulate body posture and/or direction of limb movements. Even higher doses may lead to dysarthria, i.e., the loss of vision, hearing, and finally severe tremors, coma, and/or death [95]. These severe symptoms have only been observed in people who repeatedly consumed fish that were contaminated directly by methylmercury from anthropogenic sources [94].

Because of the biochemical activity of methylmercury and thus its ability to cross the placenta, children exposed to methylmercury in utero display developmental impairments that reflect compromised brain function; these symptoms may include such things as lower IQ, decreased memory function, attention deficit, and/or impaired language skills. More serious physiological effects include motor difficulties, sensory problems, and mental retardation [96].

Physical and environmental parameters that influence methylmercury concentration in natural waters are water pH and dissolved organic carbon (DOC). Higher acidity and DOC increase methylation rates of mercury and enhance its mobility in the water, thus making it more likely to enter the food chain [97–99].

Additionally, algal blooms reduce the uptake of methylmercury in freshwater food webs [100].

Methylmercury released directly into aquatic systems can cause mass acute mercury poisoning in humans who consume contaminated fish and shellfish. Probably the most dramatic historical example of this occurred in Minimata, Japan. Minimata is considered to be one of the worst industrial disasters of all time. Between 1932 and 1968, a factory of the Chisso Corporation discharged roughly 27 tons of mercury into a waterway that fed directly into Minimata Bay. The factory was using mercury as a catalyst to produce acetaldehyde, a chemical employed in the manufacturing of plastics [101]. More than 3,000 people were “officially” recognized and reported by government officials as directly suffering from mercury intoxication. Later, however, estimates of the number of people from the contaminated area afflicted with health problems or left permanently disabled increased to two million [102]. The large difference between these two estimates of the number of Minamata Disease victims reflects the fact that a social stigma associated with the symptomologies caused denial and/or underreporting by the afflicted, the local populations, and the local/national governments.

The range and severity of the health effects from this incident of mercury poisoning were extreme. The afflictions included the various symptoms discussed above and extended to birth deformities and deaths. Public awareness of the incident became widespread at roughly the time of the birth of the environmental movement elsewhere in the world. The account of what happened was so highly publicized that mercury poisoning became known as “Minamata disease” [103, 104].

A similar event occurred in Niigata, Japan. Mercury waste from acetaldehyde production was released from the late 1950s to the early 1960s by the Shawa Denkō Corporation factory into the Agano River, 65 km upstream from Niigata. The quantity released remains unknown to this day [105]. The Minamata and Niigata examples illustrate instances where the use of inorganic mercury as a catalyst in an industrial process led to very serious impacts from methylmercury intoxication. Specifically, mercuric sulfate, HgSO_4 , was used to convert acetylene into acetaldehyde, a precursor for, inter alia, acetic acid and acetone; and mercuric chloride, HgCl_2 , was used to convert acetylene into vinyl

chloride, a precursor of polyvinyl chloride (PVC). Unfortunately in both cases a side reaction of the catalytic cycle led to the production of methylmercury, by far the most toxic form of mercury, and the methylmercury was discharged with the wastewater from the factories, with tragic consequence for segments of the local population. Such examples clarified and galvanized societies' awareness of mercury as a pollutant with potentially direct and dire human impacts. It is important also to understand that the Minamata and Niigata cases represent examples where large, direct inputs of mercury were being made to water basins of relatively small volume, and very close to large human populations. In these cases, the delivery:dilution ratio was heavily skewed toward the delivery side, and there was a high probability of frequent human interaction with the introduced mercury through both direct and indirect pathways.

A somewhat different example of mercury pollution occurred at Dryden, Ontario in Canada. In this case, the Dryden Chemical Company repeatedly discharged inorganic mercury into the Wabigoon River between 1962 and 1970. Total discharges have been estimated at ~ 9 tons. The mercury was discharged with the wastewater from a chlor-alkali plant, where once again inorganic mercury was being used, in this case to convert sodium chloride (NaCl) into chlorine and sodium hydroxide. The inorganic mercury subsequently became methylated in the natural environment (i.e., not within the plant itself), resulting in serious methylmercury pollution in the downstream freshwater system and its various aquatic components [106]. This case again involved substantial inputs of mercury directly into aquatic systems of relatively small volume and close to large human populations.

Fish and shellfish have not been the only contaminated food source associated with methylmercury poisoning in humans. Other foods such as grain [107, 108] and meat [109] have caused mercury-related health effects, the most notable of these examples being the Basra grain disaster. In the 1960s and 1970s, seed grain containing ~ 8 $\mu\text{g/g}$ mercury was shipped to Basra, Iraq. In Basra, it was coated with methylmercury as a preservative/fungicide. The seed grain was then distributed throughout Iraq with the expectation that it would be planted. However, people fed the grain to

livestock destined for human consumption. The mercury was biomagnified through the food chain from grain to livestock to humans. People also consumed the grain directly by using it to make flour for bread and related food products. The decision of people to consume the seed grain instead of planting it resulted in mass mercury poisoning. Ten thousand people died and 100,000 were severely and permanently brain damaged [107].

Humans are not the only victims of environmental methylmercury contamination. Due to a commonality of certain biochemical processes across all animal groups, methylmercury has the potential to adversely affect many wild and domesticated animals. Such effects have been most notable proximate to areas of contamination and have been most evidenced as diminished reproductive success in fish, fish-eating birds, and mammals [88, 110].

Etiology of Mercury Intoxication

As noted above, mercury has a strong tendency to bind to sulfur and especially to selenium, which are essential elements. Because of this tendency, mercury can compromise the functionality of essential sulfur-containing amino acids (cysteine and methionine) and selenium-containing amino acids (selenocysteine, selenohomocysteine, and selenomethionine). The term "essential" in this context refers to compounds that humans cannot synthesize. Such compounds must be obtained from the food people eat. The distinction between essential and non-essential amino acids is somewhat unclear, as some amino acids can be produced from others. Methionine, for example, can be converted into homocysteine, which in turn can be converted into cysteine. Thus, given an adequate supply of methionine from food, humans can produce all the cysteine they need. But humans cannot synthesize methionine and cysteine *de novo*, and for this reason the sulfur-containing amino acids are often considered to be a pool of nutritionally equivalent essential amino acids. Similar logic applies to the selenium-containing amino acids.

One of the important functions of these two groups of amino acids is their role in determining the so-called tertiary structure of proteins. Simplistically, proteins are polymers of amino acids, and the sequence of

amino acids determines the primary structure of the protein. Hydrogen bonds between sequences of amino acids (peptides) determine the localized secondary structures of protein molecules. The tertiary structure is the overall three-dimensional structure of the protein and requires that certain parts of the molecule be locked into place by various mechanisms that include disulfide bonds, which is why cysteine and methionine are so important. Selenoproteins are analogs of ordinary proteins but contain one or more selenocysteines in place of cysteine. They are common in animals, and in humans ~25 selenoproteins have been identified. Health effects associated with an inadequate supply of selenium in the diet are believed to reflect the body's inability to synthesize sufficient amounts of these selenoproteins.

Exposure Limits

The unfortunate, industrially related incidents discussed above focused the attention of both health officials and the public on the perils associated with mercury. These were cases where mercury was discharged directly into bodies of water from which the local populace removed and consumed seafood containing up to 40,000 $\mu\text{g Hg/kg}$. Such industrial events are extreme, and the resultant concentrations of mercury in fish and shellfish were far above background levels. But the fact is that mercury occurs naturally in the environment, and through perfectly natural processes it finds its way into food that people eat. Incidents such as Minamata and Niigata contributed to public awareness of health issues associated with mercury bioaccumulation and biomagnifications in food chains leading to humans and led to the question, how much is too much. Studies began showing developmental effects in children, in particular among island/coastal populations that primarily consume seafood [111–113]. Federal and global organizations (e.g., US Food and Drug Agency (FDA), US Environmental Protection Agency (EPA), United Nations Food and Agriculture Organization (FAO), and the World Health Organization (WHO)) also took notice and began instituting guidelines for the consumption of fish and shellfish. Advisories, though intended for the general population, carried particular focus on pregnant women, fetuses, and young children.

Currently the US EPA uses a Reference Dose of 0.1 $\mu\text{g methylmercury/kg body weight/day}$ as an exposure limit without recognizably adverse effects. This limit carries a safety factor of 10 from the lowest observed adverse exposure level and corresponds to a blood mercury level of 5.8 $\mu\text{g/L}$ or 5.8 parts per billion (ppb) mercury. Blood mercury levels below this value are considered to be without appreciable risk by the EPA [114]. The Joint FAO/WHO established a Provisional Tolerable Weekly Intake of Mercury (PTWI) of 1.6 μg of mercury/kg of body weight, somewhat higher than the EPA's recommendation. The WHO guideline of methylmercury intake is equivalent to a concentration in hair of 5 parts per million (ppm). Another study of mercury in hair conducted in the Seychelles Islands, where seafood consumption is significantly higher than average, found mercury levels in hair ranging from 7 to 26 ppm. The Seychelles study was supportive of the WHO guideline. Though the calculated FAO/WHO value for all adults was actually 3.3 $\mu\text{g Hg/kg}$ of body weight, the published value of 1.6 μg of mercury/kg of body weight, which was weighted in favor of the most susceptible segment of the population (i.e., pregnant women, fetuses, young children) came to be commonly cited and used. Currently, the level of concern for mercury in fish is set by the FDA at 1.0 mg Hg/kg fish tissue.

Mercury in the Oceanic Ecosystem

Mercury from both natural and anthropogenic sources finds its way into the ocean, is taken up by plankton, and then transferred to small planktivorous fish. This begins a process of food chain magnification as the mercury is transferred to larger and larger predatory fish, ultimately finding its way into top-level carnivores like the tuna, swordfish, and sharks that people eat. Such large predatory fish tend to have the highest mercury concentrations (i.e., $\mu\text{g Hg/kg}$ fish) and as such have attracted the most attention from the public, health officials, and scientists. The accumulation of methylmercury in high trophic level organisms results mainly from the ingestion of methylmercury-containing food (biomagnifications) rather than direct uptake of methylmercury from the water itself (bioaccumulation).

There are many factors that influence the concentrations of methylmercury in open ocean fish. These include size [115], age, trophic position [116, 117], physical and environmental parameters [100], and area of capture [118, 119]. There also remain large unexplained variations in the relationship of mercury concentration (i.e., $\mu\text{g Hg/kg}$ fish tissue) versus fish size. In general, one would expect that, within a given species, larger fish are older fish and have consumed more prey to attain their size. A relationship between fish size and mercury content of the flesh is evident for some marine carnivorous species such as *Seriola rivoliana* (common name, bonita or jack), *Acanthocybium solandri* (common name, wahoo, ono), *Lutjanus syagris* (common name snapper), and *Epinephelus guttatus* (red hind, grouper) [120].

The age of the fish and preferred depth of feeding appear to explain more of the variance in mercury concentration than does size [117, 118, 121, 122]. Depth of habitat and foraging were found to be highly correlated with mercury concentrations [123]. This is because dissolved organic mercury concentrations increase with depth [123]. In addition, deeper waters (i.e., below the thermocline) tend to have lower oxygen, which leads to enhanced methylation rates [124–127]. This has led to the recent conclusion that the source of methylmercury in the open ocean is the deep water column [128, 129] and not coastal runoff [130] or the euphotic zone [131]. Many large oceanic predatory fish regularly dive to great depths to forage for prey from waters having lower oxygen concentration.

Mercury and Selenium

The confusion generated by the guidelines from the various agencies, along with repeated media attention to the presence of mercury in seafood has led to significant misunderstandings concerning the safety of seafood consumption and the role of seafood in a healthy diet. This has been to the detriment of both the commercial fishing industry and the consumers who have been confused and/or discouraged from regularly eating seafood.

What are some of the reasons that the perceived risk from eating seafood is overestimated? First, there has never been a confirmed case of mercury poisoning from the consumption of tuna or any other open

ocean fish. The potential harmful effects of low levels of mercury from open ocean fish are undocumented and hypothetical. Mercury may be toxic at high levels, but not at the low levels typically found in oceanic fish. The joint advisory on seafood issued in 2004 by the FDA and EPA (www.cfsan.fda.gov/~dms/admeHg3.html) was for pregnant women, nursing mothers, and young children. It directed pregnant women, nursing mothers, and young children to avoid eating swordfish, sharks, king mackerel, and tilefish, to limit consumption of other forms of fish to two meals per week, and to limit consumption of tuna to one meal per week. There has never been an advisory directed at the general consumer to limit seafood consumption.

Scientists are now realizing that earlier studies and resulting consumer guidelines were flawed. In fact, deliberately avoiding fish may increase the risk of adverse nutritionally related health effects. The benefits of fish oils (i.e., the omega-3 polyunsaturated fatty acids) on brain development are known and widely accepted. The basis of this realization began when adverse child brain development effects were not seen in multiple follow-up studies in populations consuming ocean fish [132–134]. Omega-3 polyunsaturated fatty acids (PUFAs) are critical to normal development of the human brain and nervous system. Pregnant women and nursing mothers who avoid foodstuffs rich in omega-3 PUFAs without replacement from another source risk adverse effects on their child's brain development. The excessive caution associated with fish consumption reflected knowledge that the fetal brain is very sensitive to maternal exposure to methylmercury. It is true that methylmercury can impair selenoenzyme activities in the brain.

Further exploration, however, revealed that selenium, an essential trace element, is simultaneously present with mercury in most oceanic fish. The ratios of selenium to mercury in these fish probably explain why consumption of ocean fish is not associated with mercury intoxication [135]. In almost all species of oceanic fish tested the amount of selenium exceeded that of mercury on a molar basis [136, 137]. Selenium was first considered to be a toxin, which it is when the dose is sufficiently high. Its essential antioxidant function was discovered in 1957. It is now considered an essential trace element, with a recommended daily allowance for adults of 55 $\mu\text{g/day}$. It is found in virtually

all commercial vitamin supplements. Selenium has been shown to protect against mercury toxicity in all animal species studied. Although historically the toxicity of mercury has been attributed to its great affinity to bond to sulfur-containing amino acids in protein, the binding affinity of mercury to selenium (to form inert mercury selenide) is a million times stronger than mercury's binding affinity to sulfur. In effect then, selenium can prevent mercury from causing health problems by sequestering mercury as mercury selenide. Alternatively, however, too much mercury in the diet can actually cause a selenium deficiency.

The conclusion then is that fish are unsafe to eat only when mercury concentrations in the fish are higher than the selenium concentrations [137]. In such cases the adverse health effects may reflect a combination of the directly toxic effects of the mercury and/or a selenium deficiency caused by the fact that selenium and mercury sequester one another. The only cases where mercury to selenium ratios exceed one is in some sharks and pilot whales. Selenium is necessary for cellular function in most animals. It is required for more than 25 enzymes with important functions [138, 139]. The ability of selenium to effectively detoxify metals such as mercury was first reported in 1967 [140]. The ability of selenium to decrease mercury toxicity has been established in all species examined to date [141, 142]. The high binding affinity between mercury and selenium [143] is very likely responsible for the ability of selenium to sequester and therefore detoxify mercury. As long as the ratio of selenium to mercury in the diet is sufficiently high, the selenium can sequester the mercury and effectively render the mercury harmless [136, 144]. Molar concentrations of selenium in fish are essential factors in evaluating risks associated with dietary mercury exposure. If the selenium level is higher in the fish than the mercury level, the fish is considered safe to eat [137]. The molar ratio of selenium to mercury is quite high in the muscle of most commercially important ocean fish [137, 145–148]. Pelagic oceanic fish are rich in selenium relative to mercury. Such fish appear more likely to prevent mercury toxicity than to cause it. The old thinking was that mercury was toxic by itself; the new thinking is that selenium and mercury sequester one another. Many of the symptomologies that were previously attributed to

mercury toxicity are being reexamined as possible cases of selenium deficiency caused by mercury's role in sequestering selenium.

Future Directions

The prognoses for CFP and methylmercury are rather different. CFP is caused by a toxin that is naturally produced by certain species of marine dinoflagellates and passed up the food chain. Human activities appear to be largely unrelated to production of the gambiertoxins that are subsequently converted to various congeners of CTX. At the present time the best defense against CFP appears to be refraining from eating certain kinds of fish (e.g., barracuda) that have historically been associated with CFP. Based on extensive surveys in areas where CFP occurs, this policy would amount to erring on the side of safety but would apparently result in many harmless and nutritious fish being deleted from the menu. A preferable solution would be the development of a simple and inexpensive test to determine whether a fish contains CTX. Unfortunately, no such test currently exists, and because there are reported to be literally dozens of congeners of CTX, it is unclear that a single test could provide a reliable yes/no answer to the question. Ultimately an antibody-based assay may solve the problem, but at least at this point in time, development of such an assay is not imminent.

In the case of methylmercury, it is fair to say that very significant progress has been made since the discovery of Minamata Disease. Global production of mercury has declined by about 70% since 1970, a pattern that in no small part reflects recognition of the toxicity of mercury (especially methylmercury) and the efforts of government agencies to regulate mercury use and discharges and of industry to identify substitutes for mercury in many of its earlier applications and to reuse and recycle in cases where no substitutes exist. Probably the most important ongoing development is the controversy surrounding the health effects associated with consumption of fish and shellfish. With respect to this issue, public education is very important. The fact is that most fish and shellfish contain very little mercury. It is therefore straightforward to obtain the nutritional benefits of eating fish and shellfish without any risk from mercury intoxication.

Bioaccumulation/Biomagnifications in Food Chains. Figure 5

Molar ratio of selenium to mercury in fish from the central North Pacific near Hawaii. Dashed line corresponds to a molar ratio of 1.0 (Data from Kaneko and Ralston [137])

Remarkably, almost all fish reported to contain more than trace amounts of mercury also contain substantially more selenium than mercury (Fig. 5), the result being that consumption of those fish may actually safeguard the consumer against mercury intoxication from other sources of exposure as opposed to being a threat to human health. The exceptions to this last statement include pilot whales and mako sharks, which are not in the creel of most fishermen, not on the menu at many restaurants, and not on the dinner table of most people.

Glossary

Biochar The porous carbonaceous solid produced by thermochemical conversion of organic materials in an oxygen-depleted atmosphere which has physiochemical properties suitable for the safe and long-term storage of carbon in the environment and, potentially, soil improvement.

Black carbon The continuum of solid combustion products ranging from slightly charred degradable biomass to highly condensed, refractory soot. All components of this continuum are high in carbon content, chemically heterogeneous, and dominated by aromatic structures.

Carbon (dioxide) equivalent Common measure of global warming potential constructed by converting the emissions of the six greenhouse gases under the Kyoto Protocol of the UNFCCC into the equivalent radiative forcing units of CO₂. CO₂, N₂O, and CH₄ are the relevant Kyoto gases to be considered in evaluating biochar.

Carbon abatement (CA) The net effect of changes in greenhouse gas fluxes that result from the production and application of biochar. This can include any or all of the following: carbon stored in biochar; CO₂ equivalent emissions released during pyrolysis; offset CO₂ equivalent emissions arising from avoided fossil fuel combustion; offset CO₂ equivalent emissions from reduced chemical inputs to agriculture; change in nitrous oxide and/or methane flux through biochar addition to soils; change in carbon in soil organic matter due to biochar addition; and offset CO₂ equivalent emissions from changed operations in the field. Which of these components is included will be specified in the text.

Carbon credit Any mechanism for allocating an economic value to a unit of carbon (dioxide) abatement. The most common units are EU Allowances (EUAs) (under the EU ETS), Emission Reduction Units (ERUs) (Joint Implementation, UNFCCC), Certified Emission Reductions (CERs) (Clean Development Mechanism, UNFCCC), and Verified Emission Reductions (VERs) (voluntary carbon market).

Carbon stability factor (CSF) The proportion of the total carbon in freshly produced biochar which remains fixed as recalcitrant carbon over a defined

time period (10, 100 years, etc., as defined). A CSF of 0.75 means that 75% of the carbon in the fresh biochar remains as recalcitrant carbon over the defined time horizon, and that 25% of the carbon has been converted into CO₂.

Charcoal The solid product of natural fire and traditional biomass conversion under partially pyrolytic conditions without yielding bioenergy coproducts.

Mean residence time (MRT) Inverse of decay rate, this is the average time for which carbon in new biochar remains present in a recalcitrant form.

Net primary productivity (NPP) A measure of plant growth and the additional CO₂ fixed and stored into plant biomass over a period of, for example, 1 year; technically, it is calculated as the balance between net photosynthesis and plant (dark) respiration.

Pyrolysis-biochar system (PBS) A combination of a specified pyrolysis technology, transport, distribution and storage infrastructure and application of biochar.

Recalcitrant carbon Aromatic carbon which is resistant to chemical or biological oxidation and subsequent conversion to CO₂.

Terra preta Literally “dark earth,” these are localized soils, intensively studied, whose dark color appears to result from historic and prolonged management with charcoal, probably for the enhancement of agricultural productivity in and around the Amazon Basin.

Definition of the Subject

Biochar is the solid remains of any organic material that has been heated to at least 350°C in a zero-oxygen or oxygen-limited environment, which is intended to be mixed with soils. If the solid remains are not suitable for addition to soils, or will be burned as a fuel or used as an aggregate in construction, it is defined as char not biochar. There is a very wide range of potential biochar feedstocks, e.g., wood waste, timber, agricultural residues and wastes (straws, bagasse, manure, husks, shells, fibers, etc.), leaves, food wastes, paper and sewage sludge, green waste, distiller's grain, and many others. Pyrolysis is usually the technology of choice for

producing biochar, though biomass gasification also produces smaller char yields. Syngas and pyrolytic bio-liquids, which have a potential use as energy carriers, are produced alongside biochar.

The strongest evidence for the beneficial effects of char additions to soils arises from the *terra preta* soils of the northern Amazon, where dark, highly fertile soils with very high levels of both stable (char) carbon and organic carbon were established and remain today [1]. Char was also added historically to soils in parts of northern Europe (including Netherlands, NW Germany, and Belgium) [2]. Chars have been, and are currently being used as soil amendments in Japan and West Africa.

The contemporary interest in biochar started in the early part of the twenty-first century and arises from the bringing together of the potential benefits for soils and agriculture with the carbon storage or sequestration opportunity afforded by recalcitrant, stabilized aromatic carbon. Biochar production and deployment has the potential to do one or more of the following:

- Reduce atmospheric greenhouse gas concentrations through CO₂ removal and avoided greenhouse gas emissions (perhaps on a gigaton carbon abatement scale)
- Improve the structure, properties, and “health” of soils
- Increase crop productivity
- Provide energy (e.g., electricity from syngas, heat from syngas, power from liquid fuels)
- Safely dispose of certain waste materials with potentially useful recovered by-products
- Absorb pollutants and contaminants and reduce nitrate leaching to water courses
- Suppress soil emissions of nitrous oxide and methane

Biochar is one of only a few strategies for actually removing CO₂ from the atmosphere (in addition to reducing atmospheric emissions where the use of fossil fuels is substituted for). While this feature may not currently be a top priority, it will become increasingly important in the decades to come, as it is almost inevitable that atmospheric CO₂ concentrations are now set to exceed what is commonly regarded as a safe level

(400–450 ppm). Biochar has consequently been termed ageo-engineering option, though it is a debatable point (See [Box 1](#)).

Introduction

Contemporary biochar research originates from several different sources: (a) research on *terra preta* soils from Amazonia dating back to the middle part of the twentieth century and earlier (e.g., the pioneering work of Sombroek) [3]; (b) research on the effects of charcoal on soils and plants, with initial contributions from the early- to mid-twentieth and more significant efforts in Japan in the 1970s and 1980s; (c) research on the properties and cycling of naturally occurring black carbon and charcoal; and (d) engineering RD&D on pyrolysis and gasification. The idea of the long-term storage of carbon in a stabilized form as found in charcoal (aromatic benzene-ring-type structures) was first proposed by Seifritz in 1993 [4], though his vision was storage in suitable land formations (such as valleys) rather than on agricultural land. This proposal was somewhat ahead of its time, and it was not until the first half-decade of the twenty-first century that the climate-change agenda provided a way of bringing the quite disparate areas of soil science, agronomy, environmental science, and engineering together under the banner of “biochar”. Johannes Lehmann and Peter Read were important in making this conceptual linkage. A series of meetings took place in 2006 to 2008 which began to define and consolidate the emergent biochar community of researchers, practitioners, policy makers and entrepreneurs, including the first three meetings of the International Biochar Initiative (2007, Australia; 2008, UK; 2010, Brazil). In 2009, the first dedicated biochar book was published, edited by Lehmann and Joseph [5], and a series of national and regional meetings were held in 2009–2011, including in the USA, UK, Australia, China, Malaysia, and Brazil. Dedicated biochar research centers have now been established in the USA, Germany, New Zealand, and the UK, while existing departments, laboratories, or field stations in the disciplines of soil science, pyrolysis engineering and agronomy are increasingly turning their attention to biochar RD&D. Writing in 2010/2011, biochar has now become a distinct cross-disciplinary field of enquiry, a remarkable

achievement given that the word was not even in circulation until the mid-2000s. Several comprehensive reviews of the biochar field were published in 2009 and 2010, and these can be read alongside the current chapter [2, 6, 7].

In this chapter, biochar is reviewed from the perspective of climate change, biomass and bioenergy resources, soils and agronomy. Biochar intersects all these issues and has to be evaluated against the dominant and emerging designs and options for solving problems and creating opportunities in those separate domains. As a multipurpose product and/or as an element of a multifunctional system, the different potential functions and purposes of biochar need to be dissected and analyzed. In section “[What Is Biochar and How Can It Contribute To Carbon Mitigation?](#),” biochar is defined, and the key arguments as to why it might be useful in carbon mitigation are presented. In section “[Biochar Production](#),” the main ways in which biochar can be produced are covered, briefly describing the key technological issues and challenges. Section “[Properties of Biochar](#)” covers some of the properties of biochar. Section “[Carbon Mitigation Potential of Alternate Production Technologies](#)” provides an account of the energy and carbon balance of the pyrolysis process that is at the core of biochar as a carbon abatement strategy. Section “[Evaluating Carbon Abatement from Biochar](#)” extends this to an analysis of carbon abatement across the biomass-bioenergy-biochar lifecycle and addresses three crucial questions.

- How much potential carbon abatement might arise from biochar globally?
- How efficient is carbon abatement through biochar compared to alternative use of the same organic matter across the life-cycle of the system?
- How cost efficient is carbon abatement through biochar?

Section “[What Are the Impacts of Biochar on Soil](#)” is a detailed analysis of the impacts of biochar in soils. In section “[Conclusion: Evaluating the Sustainability of Pyrolysis-Biochar Systems](#),” some preliminary conclusions regarding biochar and its wider sustainability are presented. Finally, in section “[Future Directions for Research, Development and Demonstration](#),” some key research needs and future directions are considered.

What Is Biochar and How Can It Contribute to Carbon Mitigation?

We define biochar as the porous carbonaceous solid produced by the thermochemical conversion of organic materials in an oxygen-depleted atmosphere and which has physiochemical properties suitable for the safe and long-term storage of carbon in the environment and, potentially, soil improvement. This definition is deliberately flexible and refers to both the production of biochar and its application.

Combustion of organic matter will take place if there is too much oxygen present during thermal conversion, and the resulting solid will be ash which typically contains just a few percent of carbon by mass, in addition to compounds and elements (phosphorus, potassium, other metals, etc.). With a low-level of introduced oxygen and thermal treatment of the organic matter, gasification may take place, during which volatile organic compounds are generated and released as vapor. This energy-rich synthesis gas (“syngas”) can be cleaned and used for electricity-generation.

Pyrolysis occurs where the organic matter is subject to heat in the absence of any introduced oxygen and yields about a third of the feedstock as char (by weight), while gasification produces up to 10% char by weight. Charcoal is a type of char that has been produced (intentionally or otherwise) from wood for millennia, and much of our knowledge of biochar derives from the study of charcoal. Charcoal has also been used in soil-management practices for millennia and has well-documented benefits. While these are best observed in tropical environments – most famously in the *terra preta* soils of the Amazon – they have also been observed in temperate and semi-tropical regions.

It would be a mistake to equate biochar and charcoal however, since biochar represents a much wider group of materials which are likely to have far more variable properties than charcoal. Biochar comprises stabilized plant material in which carbon is stored mainly in a chemically recalcitrant form which will not significantly degrade through microbial activity or chemical reaction in the environment. It is this recalcitrance which is of interest from a carbon mitigation perspective since the carbon is thereby unavailable to microorganisms and does not return to the atmosphere as carbon dioxide (CO₂). But how long does

carbon remain fixed in biochar? The mean residence time (MRT, the inverse of the decay rate) is the average time for which carbon in new biochar remains present in a stabilized aromatic form. The MRT of charcoal and analogous material is in the order of millennia [8]. Biochar may therefore provide an effective long-term store of carbon in soil and thus offer a potential abatement option for anthropogenic carbon emissions [9].

Stabilization of Plant-Captured Carbon

Annually, plants draw down 15–20 times the amount of CO₂ emitted from fossil fuels (7.5 Gt C year⁻¹), up to 20% of the entire atmospheric pool. About half of this is returned immediately to the atmosphere through plant respiration, but about 60 Gt C year⁻¹ [10] is invested in new plant growth (about 45% of plant biomass is carbon) and contributes to net primary productivity (NPP). Since plant biomass is relatively constant globally, the magnitude of new plant growth must be approximately matched by harvest, litterfall, exudation by roots, etc. The annual CO₂ release from decomposition of these products by natural pathways and human cycling of plant-derived materials and products roughly equals NPP. The annual return of carbon to the atmosphere from the decomposition of all prior cohorts of plant material is thus approximately equal to NPP.

Intercepting and stabilizing plant-biomass production reduces the return of carbon to the atmosphere, with a relative reduction in atmospheric CO₂ (see Fig. 1). This reduction can be quite immediate if the default rate of decomposition is months to years, as it is for the dominant portion of biomass returned to soil in managed (agricultural and forest) ecosystems. Controlled charring (pyrolysis) can convert up to half of the carbon in plant biomass into chemical forms that are recalcitrant and, in principle, managed soils have a capacity to store pyrolyzed biomass at a rate significant in terms of emissions of carbon from fossil fuel.

The conversion of carbon in plant biomass to charcoal during natural fire is only about 1–5%, but the high level of stability established for such material in soil, which is generally a highly active biological medium, leads to expectation for similar stability in deliberately produced biochar. Biochar, deployed as a “carbon-negative” technology at the scale of 1 Gt C year⁻¹, would

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 1

Schematic illustrating the pyrolysis-biochar concept [9] (With permission from Nature Publishing)

be equivalent to expanding the natural cycle of fire-derived charcoal storage in geographic terms and increasing its global magnitude by a factor of 4–20 [11].

Methane (CH_4) and nitrous oxide (N_2O) are the second- and third-largest contributors to radiative forcing of climate change after CO_2 . Soil is a key source of both gases, which are emitted through natural microbial processes. The global significance of these processes has increased with agricultural expansion since higher CH_4 emission is associated with flooded soil conditions and with an enhanced nitrogen cycle (increased N_2O emissions) provided by the use of (synthetic) fertilizer, manures, and slurry. Since both CH_4 and N_2O are also associated in part with organic matter decomposition, stabilizing degradable organic matter could have a direct impact on soil-based emissions of these gases. Interventions in the nutrient or water balance of soil through changes in the dynamics of water

in soil, or through the adsorption of nitrogen (as ammonium) may indirectly modify emissions of these gases from the soil.

To be a significant response to climate change, carbon abatement on a scale of millions of tons needs to occur, preferably hundreds of millions of tons. To intercept NPP and produce biochar at this scale presents a practical challenge, but still only involves a small fraction of total plant NPP ($60 \text{ Gt C year}^{-1}$) of which 30% is already calculated to be “co-opted” by humans [12]. Increased efficiency of biomass recovery in managed ecosystems, diversion of biomass from current uses where it has a low value, and utilization of used biomass (organic waste) streams provide three ways in which it might be achieved. The fourth option is to sustainably harvest more biomass, which might be achieved by growing more productive plants, increasing the area of managed land, or adjusting harvesting

regimes. Clearly, demonstrable effects on NPP arising from the deployment of biochar could be factored into such strategies.

Indirect CO₂ Equivalent Impacts

Biochar can improve the pore-size distribution of soils, resulting in an improved retention of plant-available nitrogen in the soil, increasing plant N uptake and fertilizer-use efficiency. This implies lower fertilizer requirement and lower eutrophication risks. If the accumulation of biochar results in beneficial change in pore-size distribution, it would result in a more permanent change than can be achieved through the effects of degradable and thus transient organic matter that can be used to condition soil.

The release of nitrogen by soil microbes from decomposition of crop residues in the low-growth winter period (in temperate regions) is a key source of nitrogen loss to water and the atmosphere. Increasing the use-efficiency of nitrogen in recoverable crop residues is therefore of relevance to eutrophication through leaching, and N₂O emissions.

Changing the abundance or physical position of aerobic space in soil (with respect to loci of microbial activity) has the potential to mitigate CH₄ emission. The emission of N₂O from soil could be suppressed by adsorption of nitrogen in the form of ammonium (NH₄⁺). Emissions of both CH₄ and N₂O are notoriously variable both temporally and spatially, and are also sensitive to soil pH. However, these mechanisms may be relevant in the suppression of CH₄ and N₂O by biochar observed at certain locations, or under certain controlled conditions [13].

The Haber–Bosch process used to fix atmospheric nitrogen into solid soluble (ammonium) form is an energy intensive process that accounts for about 40% GHG emissions associated with arable agriculture. Typical use-efficiency for fertilizer nitrogen globally is 30–50% [14] attributable to leaching, immobilization and gaseous loss, and leaching. Technologies that improve the management of these processes through the soil can therefore offer an indirect gain in agricultural carbon-equivalent balance.

Liming of agricultural soil also transfers carbon from the geological pool to the atmosphere through production (calcining of limestone) and subsequent

neutralization in the soil [15, 16]. The alkalinity typical of biochar can potentially substitute for the use of lime in the management of soil pH without emission of CO₂ [13].

Reliable and secure storage for annual and large cumulative amounts of biochar would have to be available, and while simple burial (for example, in landfill or disused mines) has been considered [4], these possibilities would be limited, costly and potentially dangerous. The broader land surface, and in particular soils that are already actively managed, may therefore provide the required capacity for a large and enduring strategy for storing carbon in biochar [17]. The key assumptions are that the estimates for stability of charcoal made so far are typical and accurate, that biochar from modern pyrolysis technologies using more diverse feedstock exhibits broadly similar levels of stability as natural charcoal, and that appropriate feedstocks can be provided sustainably and without adverse environmental or sociopolitical impacts.

Box 1: Is Biochar Geoengineering?

Geoengineering has been defined as the “deliberate large-scale manipulation of the planetary environment to counteract anthropogenic climate change” [18]. Biochar is regarded as a form of geoengineering by the Royal Society of London, along with afforestation and associated removal of wood for long-term applications and a range of physiochemical methods, including direct air capture, ocean fertilization, ocean alkalinity enhancement, etc. This is because, at a large enough scale, biochar could have a noticeable influence upon the global carbon cycle. Yet, there are reasons why using the moniker geoengineering for biochar is misleading. Firstly, biochar might be a small-scale intervention. Secondly, biochar is not solely concerned with moderating global warming, and there will be instances where its main function is for agronomic purposes and soil improvement, water retention, leachate reduction, or treating contaminated land. Evaluating such projects as geoengineering could be misleading and result in unhelpful comparisons with very different technologies. In many cases, better comparisons can be made between the use of agricultural and organic residues and wastes for composting, incineration, gasification, second generation fermentation, anaerobic digestion, and biochar production.

Biochar Production

Processes

There are several processes which can be used to produce biochar, pyrolysis being the most common. Pyrolysis is a thermochemical decomposition process in which organic material is converted into a carbon-rich solid and volatile matter by heating in the absence of oxygen [19]. The solid product, char or biochar, is generally of high carbon content and may contain around half the total carbon of the original organic matter. The volatiles can be partly condensed to give a liquid fraction leaving a mixture of so-called “non-condensable” gases. Each of the three product streams from pyrolysis – solid, liquid, and gas – can have properties and uses that provide value from the process. There are two main classes of pyrolysis process as well as a number of other more or less related technologies that may be considered for biochar production.

Fast pyrolysis is characterized by high heating rates and short vapor residence times. This generally requires a feedstock prepared as small particle sizes, and a reactor design that removes the vapors quickly from the presence of the hot solids, typically at around 500°C, leading to high yields of liquid products with low char yields. There are a number of established commercial processes (as well as many R&D examples) where the target products are liquids – bio-oils – although biochar from such processes has also been studied [20]. The area of bio-oil from fast pyrolysis has been extensively reviewed [21, 22].

Of more interest for biochar production is slow pyrolysis, which can be divided into traditional charcoal making and more modern processes. It is characterized by slower heating rates, relatively long solid and vapor residence times and usually a lower temperature than fast pyrolysis, around typically 400°C. The target product is generally the char, but this will always be accompanied by liquid and gas products, although these are not always recovered.

Traditional processes using pits, mounds, or kilns, generally involve some direct combustion of the biomass, usually wood, as heat source in the kiln, which reduces the char yield. Liquid and gas products are often not collected but escape as smoke. As well as particulates and carbon dioxide, other greenhouse gases such as methane may be emitted, as well as

other hydrocarbons, and amines, leading to a net positive radiative forcing effect even if the biochar product is used for carbon storage [24]. Hence, traditional charcoal-making techniques are not generally compatible with the objectives of pyrolysis-biochar systems (PBS) for carbon abatement.

Industrial-scale charcoal-making processes, using large retorts operated in batch or continuous modes, achieve higher char yields and avoid most of the issues of emissions by allowing recovery of organic liquid products and recirculation of combustible gases to provide process heat, either internally or externally [26]. Other developments have led to slow pyrolysis technologies which are of most interest for biochar production. These are generally based on a horizontal tubular kiln design, where the biomass is moved at a controlled rate through the kiln and include agitated drum kilns, rotary kilns, and screw pyrolyzers [27], as well as some gravity-driven designs. In several cases, these have been adapted for biomass pyrolysis from original uses such as the coking of coal with production of “town gas” or the extraction of hydrocarbons from oil shale. Although some of these technologies have well-established commercial applications, production of biochar is not yet one of them, and only limited reviews are available [27, 28]. Other technologies that may be considered for biochar production include flash pyrolysis (cf. fast pyrolysis but shorter residence times), intermediate pyrolysis (cf. slow pyrolysis with improved heat transfer, allowing faster throughput), flash carbonization (partial combustion in pressurized reactor), gasification (partial combustion in a gas flow), and hydrothermal carbonization (aqueous process at high temperature and pressure with catalysis) [28]. Typical values and reported ranges for key process variables and product yields of slow, intermediate, and fast pyrolysis processes are shown in Table 1 [28]).

Products

Composition of the three typical product streams from pyrolysis processes, solids, liquids, and gases, will vary with feedstock, process design, and conditions but can be generalized as follows. The solid product, char or biochar, has a varying carbon content, typically ranging from 60 to 90% [29]. In terms of proximate analysis, the char consists of four major components; fixed

Biochar, Tool for Climate Change Mitigation and Soil Management. Table 1 Scope of pyrolysis process control and yield ranges

Process	Slow pyrolysis	Intermediate pyrolysis	Fast pyrolysis
<i>Temperature</i> (in degrees centigrade)			
Range	250–750	320–500	400–750

<i>Gas</i>			
Range	0–60	9–32	5–60
Typical	20–50	20–30	10–30

Based on review of over 30 literature sources [28]

carbon, volatile carbon, ash and moisture. Energy contents of biochar range typically 20–30 MJ kg⁻¹ (Higher Heating Value (HHV), [28]).

Liquid products from biomass pyrolysis are frequently termed bio-oil. However, this is a somewhat confusing term as the organic liquid product is generally hydrophilic, containing many oxygenated compounds, and is present sometimes as a single aqueous phase and sometimes phase-separated, together with water produced in the pyrolysis reaction or remaining from the feedstock [19]. Energy contents of bio-oils range typically from 15 to 30 MJ kg⁻¹ (HHV, [28]), but figures quoted may be given after a degree of purification. The gas product is termed synthesis gas, shortened to syngas. It is typically a mixture of carbon dioxide (9–55% by volume), carbon monoxide (16–51%), hydrogen (2–43%), methane (4–11%), and small amounts of higher hydrocarbons [28]. Literature values for syngas energy content ranges are sparse,

partly due to varying composition during processing and the presence of inert gas, with available values ranging from 8 to 15 MJ kg⁻¹ (HHV, [28]).

Effect of Feedstock and Process Variables

The nature and preparation of pyrolysis feedstocks as well as the process conditions used influence both the composition and distribution of products. The main effects are caused by feedstock properties, the gas environment, and temperature control; and are summarized here for slow pyrolysis [26].

High lignin biomass will tend to give higher char yields, with other components leading to more liquid and gas products. Minerals present in the ash can have a catalytic effect by increasing char yields in some cases. Moisture can have a positive or negative influence on char yields depending on conditions. Larger particle size can increase char yields by restricting vapor disengagement and increasing the scope for secondary, char-forming reactions.

Factors affecting the gas environment that lead to a longer contact time between hot solids (feedstock or char) and primary vapor products lead to increased char yields resulting from secondary char-forming reactions at the hot surface. These factors include particle size, heating rate, and gas flow rate; increased pressure has a similar effect.

Temperature control is one of the most important operational variable, particularly peak temperature. Higher peak temperatures lead to lower char yields and higher liquid yields. For instance, a typical biomass pyrolysis might yield 38% biochar by weight on a dry basis at 350°C, but only 27% when heated at 550°C [30]. Heating rates have a smaller and inconsistent effect on slow pyrolysis. Increasing residence time at peak temperature will lead to lower char yield, but again this is a smaller effect than temperature itself.

Temperature also influences the composition and structure of the biochar formed. Higher temperatures and longer residence times lead to chars with higher concentrations of carbon and fixed carbon (determined by proximate analysis), as more volatile matter is driven off; pore structure and surface area also develop with more severe conditions. Figure 2 shows some of these temperature effects, including the effect on elemental composition of char, in a series of

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 2

Effects of temperature and heating rate on (a) char yield, and (b) carbon, hydrogen, and oxygen content of beech chars. Solid and dashed lines are 2°C and 10°C min⁻¹ heating, respectively [26] (Reproduced with permission from the American Chemical Society)

experiments with pyrolysed beech-wood [26]. Note that the complementary decrease in char (residue) yield and increase in fixed-carbon content at successively higher temperatures leads to a plateau in the fixed-carbon yield above about 400°C in this example. The relationship between fixed-carbon and soil-carbon stability is not yet clear [30].

Energy Balance

During pyrolysis, components of the biomass feedstock react by different pathways contributing to the complex products observed. Individual reactions may be endo- or exothermic and the combined process may also be endo- or exothermic depending on conditions of reaction [26]. Even when conditions favor exothermic reactions, initial heating to achieve onset temperature is required. Heat input may be provided by an external heat source, by partial oxidation of the feedstock, or by recycling and combustion of one of the product streams.

In conceptual designs for pyrolysis-biochar systems, the syngas, bio-oil, or combined gas/vapor stream are the preferred energy sources for the process. Data for process energy is not generally available in the literature but estimates suggest a requirement in the order of 10% of the energy value of the dry feedstock.

In most cases, the product distributions will leave an excess of energy in the gas and/or liquid streams which can be used for electrical generation or exported heat, but note that the higher the biochar yield obtained, the lower this excess energy will be, a significant point for the economics of the process.

Properties of Biochar

Cation Exchange Capacity

Biochar has the capacity to exchange cations (e.g., ammonium, NH₄⁺) with soil solution, and thereby store crop nutrients. The extent of this cation exchange capacity (CEC) is effectively absent at very low pH and increases at higher pH [32]. Experimental results show that the CEC of fresh biochar is typically low but increases with time as the biochar ages in the presence of oxygen and water [33–35].

Specific Surface Area

Biochar has a very high specific surface area (SSA) of several hundred m² g⁻¹ to a thousand m² g⁻¹ (Fig. 3). The main parameters influencing SSA are pyrolysis temperature, heating rate, residence time, and presence of active reagents (e.g., steam, CO₂, O₂, etc.). Figure 3a shows that the total surface area of biochar from most

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 3
Biochar surface area (a) plotted against treatment temperature and (b) its apparent relationship with micropore volume [36] (Reproduced with permission from Earthscan Ltd.)

feedstocks tends to increase with increasing pyrolysis temperature. This is mainly due to the development of micropores that are responsible for most of the surface area, see Fig. 3b.

At present, it is not clear whether the additional surface area presented by micropores plays as important role in soils as macropores and, therefore, whether it is beneficial to produce a biochar with very high SSA. It may be possible to produce biochar with high SSA in the macropore range. However, the physical structure of biochar tends to be defined by the starting material, so fine milling or compaction of the feedstock before pyrolysis is necessary to achieve a well-defined macroporous product [37].

Contaminants

There are two main potential sources of contamination in biochar: feedstock and the conversion process. Depending on the origin and nature of the pyrolysis feedstock, biochar may contain contaminants such as heavy metals (potential toxic elements, PTEs) and organic compounds. Some of these compounds will undergo changes in the conversion process and might be destroyed (or converted to benign compounds), while others will remain unchanged or give rise to potentially harmful substances. In addition to the contaminants introduced in the feedstock, some contaminants can also be formed in the conversion (pyrolysis) process. These include polycyclic aromatic hydrocarbons (PAH) and potentially, in some cases, dioxins. Additionally, the physical form of pyrolysis products may present a direct health risk, and increase or decrease the risk posed by elements, compounds, or crystalline material both in feedstock or formed during pyrolysis.

Heavy Metals

Heavy metals present in the feedstock (e.g., MSW, sewage sludge, treated wood, etc.) are most likely to remain and concentrate in the biochar (with lower char yields, resulting in higher concentration of PTEs) [38–42]. Therefore, careful selection and analysis of feedstock is necessary to avoid contamination of biochar with increased levels of heavy metals. Heavy metals are stable materials and therefore retained (conserved) during volatilization of associated organic molecules. The majority of metals will therefore be present as ash within

biochar (together with nutrient elements such as phosphorus and potassium). It may thus be possible to manipulate contaminant loadings through selective removal of ash [43]. Alternatively, it has been shown that high-temperature pyrolysis can release heavy metals from the solid product, thereby yielding char with lower loading of these contaminants [44].

Polycyclic Aromatic Hydrocarbons (PAHs)

PAHs can be formed from any carbonaceous feedstock. The major chemical pathways for (PAHs) formation in the pyrolysis process are the high-temperature secondary and tertiary pyrolysis reactions (homogeneous and heterogeneous), as shown in Figs. 4 and 5 [163]. The formation of these tertiary pyrolysis products increases with the pyrolysis severity (i.e., temperature and residence time) and becomes significant at temperatures around 750°C.

However, there exists also a second, less explored route for PAH formation. Evolution of PAHs from the solid substrate has been reported in the temperature range of 400–600°C [43, 45]. This pathway yields predominantly lower molecular-weight PAHs, although higher molecular-weight PAHs, such as benzo(a)pyrene, are also formed [45–47].

As the optimum temperature for biochar production is likely to lie in the region 450–550°C, in a well-controlled system (without hotspots), formation of PAH would proceed mainly by the evolution from solid substrates. PAH formation in the gas phase should be minimal due to the low pyrolysis temperature. Data on PAH content in pyrolysis char is scarce but indicate that the concentration and composition of PAHs in biochar are feedstock dependent [49]. Other data show that PAH concentrations in biochar produced from untreated biomass at temperatures of up to 600°C are considerably lower than those in urban soils in England, in the order of 10–100 mg kg⁻¹ [50]. Biochar produced from chemically treated biomass is liable to contain considerably higher levels of PAHs than biochar from virgin feedstock due to the possibility of indigenous PAHs apparent in a study of biochar produced from railway sleepers previously treated with tar and creosote [49]. Available published data on the concentration of benzo(a)pyrene, one of the most toxic PAH compounds, is shown in Table 2.

Birch char	Pine char	Pine sleeper char	Urban soil (England)	Rural soil (England)
310	570	4,040	714	67

Dioxins

Dioxins, unlike PAHs (which can be formed from any carbonaceous feedstock) require chlorine for their formation. Consequently, only biochar produced from feedstock containing significant amounts of chlorine (e.g. halogenated plastics) could be prone to generation of dioxins under certain conditions. The dioxin

formation process is heavily dependent on the temperature history of the pyrolysis products, and relatively high temperatures (around 750°C) are required for the formation of dioxin precursors (chlorinated benzenes and phenols). Therefore, it is unlikely that biochar produced by pyrolysis at temperatures between 450–550°C would contain dioxins in significant amounts even when produced from feedstock containing chlorine, despite the fact that dioxins can be formed from their precursors in this temperature range. The only exception would be biochar produced from feedstock already contaminated by dioxins or dioxin precursors.

Stability

The stability of biochar is one of its key properties as it determines its potential for long-term storage of carbon. However, despite its importance, there is no recognized way of determining stability of biochar. It is very difficult to predict stability of biochar over timescales relevant to carbon sequestration, i.e., centuries to millennia. This difficulty stems from the diversity of processes (biological, chemical, and physical) responsible for biochar degradation in the environment and the wide range of properties biochar from different sources pose. It seems that simple correlation of long-term biochar stability with any particular physical or chemical property of biochar is difficult, and new methods, such as accelerated aging, are being investigated. Preliminary results have shown that high levels of stability can be achieved in a wide range of production conditions [30].

Carbon Mitigation Potential of Alternate Production Technologies

The overall effect of pyrolysis-biochar production on carbon abatement, prior to soil incorporation, can be described as the sum of two main factors: the carbon stored in biochar (related to CO₂ removed from the atmosphere) and the CO₂ emissions avoided through substitution of fossil fuels by combustion of pyrolysis products for energy. In calculating avoided emissions, a baseline case needs to be established for comparison, selection of which can have a large impact on the results. There are three elements for selecting a baseline:

1. *Carbon intensity of displaced fossil fuel energy.* Avoided CO₂ emissions are calculated relative to

the average CO₂ equivalent emissions (including contributions of CH₄ and N₂O) from generation of grid electricity (or that from a specific facility). The carbon dioxide emission factor (CEF) of the grid varies over time with the mix of fuels used. In the UK, it has decreased over recent decades with the trend away from coal toward use of natural gas. Expressed as kg CO₂eq kWh⁻¹ electricity, CEF has fallen from 0.78 in 1990 to 0.55 in 2007 [52]. Given this trend, the UK government recommends using a CEF of 0.43 kgCO₂eq kWh⁻¹ for comparisons when considering renewable electricity development [53]. The actual CEF value, e.g., 0.5 kgCO₂eq kWh⁻¹ in 2008, could also be used. The most appropriate CEF would be employed in a specific case-study context. It will be less for an energy system that is less reliant upon coal and other fossil fuels.

2. *Carbon neutrality or otherwise of biomass system.* Combustion of biomass for energy generation releases c. 99% of plant carbon as CO₂; it is conventionally assumed that the same quantity of biomass is replanted (without incurring any additional greenhouse gas emissions), hence the same quantity of CO₂ is taken up by the growing plants and the system is “carbon-neutral”. Yet, if direct or indirect land-use change is entailed, carbon neutrality cannot be assumed: for instance, change from managed grassland (with c. 80 tC ha⁻¹) to energy-crop cultivation will involve immediate loss of CO₂ due to soil disturbance. Depending upon the energy crop, the equilibrium soil organic carbon content may decrease (e.g., to 45 tC ha⁻¹ in a wheat for bioethanol context) or possibly increase (e.g., by up to 20 tC ha⁻¹ over 20 years in the case of Miscanthus) [54]. It is therefore more accurate to include considerations of land-use change and the feedstock carbon cycle explicitly. Below we calculate the net carbon abatement from PBS assuming biomass replacement (carbon neutrality) and no replacement.
3. *Carbon Stability Factor (CSF) of biochar.* The CSF is defined as the proportion of the total carbon in freshly produced biochar which remains fixed as recalcitrant carbon over a defined time period (see Glossary). As yet, little information exists on the actual CSF of specific biochar samples due to

scientific uncertainties over biochar stability. A further uncertainty is the selection of the appropriate time period over which the stability is measured. Previous studies have used a range of values of the CSF from 0.68 over 100 years [55], 0.8 (time period undefined) [56], 1.0 (time period undefined) [57], 0.75 over 10 years [58], and 1.0 over 10 years [59]. As yet, there is no convention on the definition, measurement, and time horizon for reporting the CSF. To a certain extent, the selection of the time period is subjective and influenced by the decision-makers' preferences. In this review, we have adopted a time period of 100 years which is a compromise between the (multi-) millennial timescale of the climate system and the decadal (and frequently shorter) timescale of commercial and policy decision making. This also follows the convention of assessing Global Warming Potentials (GWP) to compare the radiative forcing of different GHGs over 100 years.

Equation 1 can be used to calculate the net carbon abatement arising from for combustion, PBS, or soil incorporation of biomass:

$$\text{CO}_{2\text{na}} = \text{CO}_{2\text{av}} + \text{CO}_{2\text{fix}} - \text{CO}_{2\text{rel}} \quad (1)$$

where:

$\text{CO}_{2\text{na}}$ is net carbon eq. abatement

$\text{CO}_{2\text{av}}$ is carbon eq. emissions avoided by replacement of fossil fuels

$\text{CO}_{2\text{fix}}$ is carbon eq. fixed in the long-term (100 years)

$\text{CO}_{2\text{rel}}$ is carbon eq. released by the biomass feedstock processing

(All expressed in $\text{tCO}_2\text{eq.t}^{-1}$ feedstock).

Meanwhile:

$$\text{CO}_{2\text{fix}(100)} = \text{BM}_{\text{tot}} \times \text{BC}_{\text{yield}} \times \text{CO}_{2\text{tot}} \times \text{CSF} \quad (2)$$

where:

$\text{CO}_{2\text{fix}(100)}$ is CO_2 eq. fixed over 100 years

BM_{tot} is biomass total dry weight

BC_{yield} is biochar yield (ratio)

$\text{CO}_{2\text{tot}}$ is total CO_2 eq. content of fresh biochar

CSF is carbon stability factor over 100 years

(All expressed in $\text{tCO}_2\text{eq.t}^{-1}$ feedstock).

Data for the example of 1 t of straw is given in Table 3. It can be seen that if combustion is used, 1.65 tCO_2 is released immediately, but there is an avoided emission of 0.66 tCO_2 arising from the substitution of fossil fuels (assuming a CEF of 0.5 $\text{kgCO}_2\text{eq.kWheq}^{-1}$). The net CO_2 emission, assuming that there is no biomass replacement, is therefore c. 1 $\text{tCO}_2 \text{t}^{-1}$ feedstock. If the same 1 t of straw is pyrolysed to produce biochar, the net CO_2 emission is lower at 0.45 $\text{tCO}_2 \text{t}^{-1}$, assuming electricity generation from PBS is feasible. If no electricity cogeneration is possible, the net emission increases to 0.73 $\text{tCO}_2 \text{t}^{-1}$, still lower than combustion (though obviously without the benefit of electricity generation). If full biomass replacement is assumed, biomass combustion and PBS both deliver net carbon abatement, though the biochar option more so.

If the alternative use of the straw is for incorporation into the soil however then the emission of CO_2 arising from decomposition would be slower. At day 1, 1.65 t of CO_2 remains in the biomass, and if we assume an exponential decay with a decay constant of 1.0, then after 4 years the vast majority of the straw has mineralized. Assuming that 5% of the straw biomass is stabilized as long-term soil carbon, then the direct incorporation abates more carbon from day 1 to 6 months. After that time, however, PBS with electricity generation and no biomass replacement abates more carbon, while after 1 year PBS without electricity generation and with no biomass replacement achieves higher carbon abatement than direct incorporation. The analysis is more complicated in the case of biomass replacement and is not attempted here. Clearly, this result is heavily dependent upon the decay function, and constant and slower rates of decomposition would give very different results under which direct incorporation would be more "competitive" in terms of carbon abatement relative to combustion and PBS.

In effect, pyrolysis has an associated "carbon debt" to pay-off due to release of CO_2 during pyrolytic conversion. The time period of this "carbon debt" is sensitive to the time horizon selected for measuring the CSF. If a shorter time horizon is chosen in measuring the CSF, then the carbon debt will appear to be smaller because the PBS CA will be larger, and vice versa. It is therefore important when evaluating options to be clear about what the PBS option is being compared

Biochar, Tool for Climate Change Mitigation and Soil Management. Table 3 Simple calculation of carbon stored and avoided CO₂ emissions arising from pyrolysis-biochar, combustion, and direct field incorporation for one oven dry ton of straw

Indicator	Combustion	Pyrolysis-biochar (with electricity generation)	Pyrolysis-biochar (no electricity generation)	Direct incorporation of straw into field ^a

^bAssumes that 55% of the carbon in the feedstock is stabilized over 100 years

to, what the CSF and time period is, and to use these numbers to calculate the carbon debt of PBS.

A simplified model was developed to calculate net carbon abatement for slow, intermediate and fast pyrolysis [28]. The data required for the model (Table 4) were gathered in a comprehensive literature review complemented by direct communication with relevant experts [36, 58, 60–64]. Model outputs are all expressed on a feedstock dry weight basis. A default value of 33% for electrical conversion efficiency of the

main model output data is assumed but with no use of spare process heat (beyond drying the feedstock). The CEF used is 0.43 kgCO₂eq kWh⁻¹ and the results are shown in Table 5.

Results of the model show that fast pyrolysis may give the highest electrical energy product. This is due to the high liquid (oil) yields from the process, which can then be used for power generation. On the other hand, the electrical energy product is lowest for the slow pyrolysis process, where much of the energy value of

Biochar, Tool for Climate Change Mitigation and Soil Management. Table 4 Data required for the pyrolysis process model

Carbon content (%)	72.3	70.0*	78.0*

* = Estimated. See text for sources of other figures

the feedstock is stored in the biochar product. Abatement is greatest for slow pyrolysis, where most carbon is retained in biochar, and least for fast pyrolysis, where char yield is low. The values in Table 5 largely agree with those in Table 3, both in terms of energy product and net CO₂ abatement, with a 20% difference in calculated net carbon abatement for slow pyrolysis with associated energy generation.

“Carbon-Negative” Energy?

It has sometimes been claimed that PBS is a “carbon-negative” energy system, this being an extrapolation from “carbon-neutral” bioenergy systems. Using Eq. 2, and assuming that BM_{tot} is 1 t, BC_{Yield} is 0.4, CO_{2tot} is 0.85 and CSF is 0.75, then the CO_{2fix(100)} is

0.935 tCO₂eq.t⁻¹ (assuming biomass used is then replaced). From Table 4, this is associated with 380 kWh electricity generation, hence, it can be argued that PBS is not only carbon neutral, but in fact a carbon-negative system. This is technically correct but only under the assumption of biomass replacement, namely that the same quantity of carbon in the biomass is taken up as CO₂ through subsequent photosynthesis, and no other land-use emissions are entailed. Furthermore, since PBS is currently an inefficient way of generating electricity, the moniker “carbon-negative energy” can be misleading and generate confusion. If the prime intention is to generate electricity, it is likely far better in most cases to utilize a more efficient conversion technology than pyrolysis.

Biochar, Tool for Climate Change Mitigation and Soil Management. Table 5 Pyrolysis process model results (assumes carbon neutral bioenergy)

Model outputs, carbon stability factor 0.75	Slow pyrolysis	Intermediate pyrolysis	Fast pyrolysis
Energy product (kWh eq kg ⁻¹ oven dry feedstock)	0.38	0.56	1.18
Net CO ₂ abatement (kg CO ₂ eq kg ⁻¹ oven dry feedstock) Pyrolysis	0.96	0.88	0.80
Combustion	0.67	0.63	0.75

Evaluating Carbon Abatement from Biochar

In order to determine the importance of a carbon abatement strategy from PBS (or variants thereof, such as Gasification-Biochar Systems, GBS), a number of questions need to be addressed, taking a systems-wide view, including techniques such as resource assessment, land-use modeling, Life-cycle Assessment and Techno-Economic Modeling.

- How much potential carbon abatement might arise from PBS globally?
- How efficient is carbon abatement through PBS compared to alternative use of the same organic matter across the life-cycle of the system?
- How cost efficient is carbon abatement through PBS in economic terms?

What Is the Potential Carbon Abatement Level?

Carbon abatement from biochar is a function of the amount of biochar produced which, in turn, is a function of the amount of biomass or other organic matter that is available. The resource pyramid approach [65] can be used to distinguish between “theoretical available resources” (i.e., the total amount which exists), “realistic available resources” (which applies a first level of pragmatic judgment to limit the supply), and “viable available resources” (which applies a second level of pragmatic judgment to further limit

supply, taking particular account of likely or possible other demands in the market place). Even so, resource availability scenarios are likely to be necessary to account for irreducible uncertainties in future supply and demand (such as scenarios reflecting lower supply, higher supply, and very high supply of feedstocks available for pyrolysis, or scenarios which reflect low, medium, and high levels of competition for any available biomass for uses other than PBS).

Lehmann et al. [17] estimate that current global *potential* production of biochar is 0.6 ± 0.1 gigatons (Gt) per year (10^9 t or PgC year⁻¹). Lenton [66] argues that the present potential for biochar production from agricultural wastes, forestry fellings, and from shifting agriculture (“slash and char”) is somewhat higher than in [17], increasing the potential carbon abatement through biochar to 0.77–0.87 Gt C (PgC) year⁻¹. Lehmann et al. [17] estimate that by 2100, production of biochar could reach between 5.5 and 9.5 Gt year⁻¹, assuming that biomass is grown specifically for the purpose of PBS. There are very large uncertainties attached to these numbers however, arising from competition for land-use, competition for use of biofuels, agricultural residues, and organic wastes, and a huge divergence (of nearly 1,000%) in different expert estimates of the potential future global supply of biomass for bioenergy purposes (see Box 2). Roberts et al. [56] arrive at a much smaller value for global CA (0.65 Gt CO₂ year⁻¹ or 0.18 Gt C year⁻¹) under the assumption that 50% of the 1.5 billion tons of currently unused crop residues globally is utilized for producing biochar. This might contribute 4% of the carbon reductions that are required globally by 2050 to limit climate change. However, after reviewing the literature on the potential production of biomass for bioenergy by 2100, Lenton [66] arrives at a carbon-abatement value from biochar that compares reasonably well with the larger Lehmann et al. value. He notes the potential constraint in carbon storage capacity in soil arising from biochar addition by about 2100, even assuming a high loading of 140 tC ha⁻¹.

Woolf et al. [68] have created and linked a global biomass feedstock availability model and a pyrolysis biochar production model, and calculate that between 1 and 1.8 Gt C year⁻¹ is feasible by about 2050 from the biochar mitigation option. The range is explained by the use of three different scenarios of biomass supply;

Box 2: Estimates of the Global Potential of Biofuels

A review by the OECD identifies four potential sources of bioenergy: additional land brought into production; crop residues; forest residues; and other organic waste (plant and animal) [70]. The OECD report suggests that, globally, 0.44 Gha is the upper limit on the land area that could be made available for dedicated bioenergy crop production by 2050. Models of land availability tend to underestimate the land that is already in use (by 10–20%), while overestimating the amount of land that could be brought into production. Limited water availability and competition for food and fiber production are frequently overlooked. The OECD estimate on new land available for bioenergy cultivation compares with the average of 0.59 Gha calculated from 11 studies reviewed [71].

The OECD report estimates that the total bioenergy available from the 0.44 Gha of new land is 100 EJ year^{-1} . The potential for marginal and degraded land is put at $29\text{--}39 \text{ EJ year}^{-1}$. As for crop residues, only 25–33% of residues are available for extraction because of competing uses and the need to return some to soil for nutrient replacement. Using yields from IIASA [72], bioenergy from crop residues is estimated at 35 EJ year^{-1} in 2050. The IIASA study estimates bioenergy from forestry residues to be 91 EJ year^{-1} , while other organic residues and wastes are expensive to collect, hence the potential is limited to 10 EJ year^{-1} by 2050 [73]. All in all, the OECD estimates that the primary energy available for heat, electricity, and motive power that could technically be made available globally is 245 EJ year^{-1} , which is at the lower end of the range reported by the IPCC in its Fourth Assessment Report ($125\text{--}760 \text{ EJ year}^{-1}$) [74].

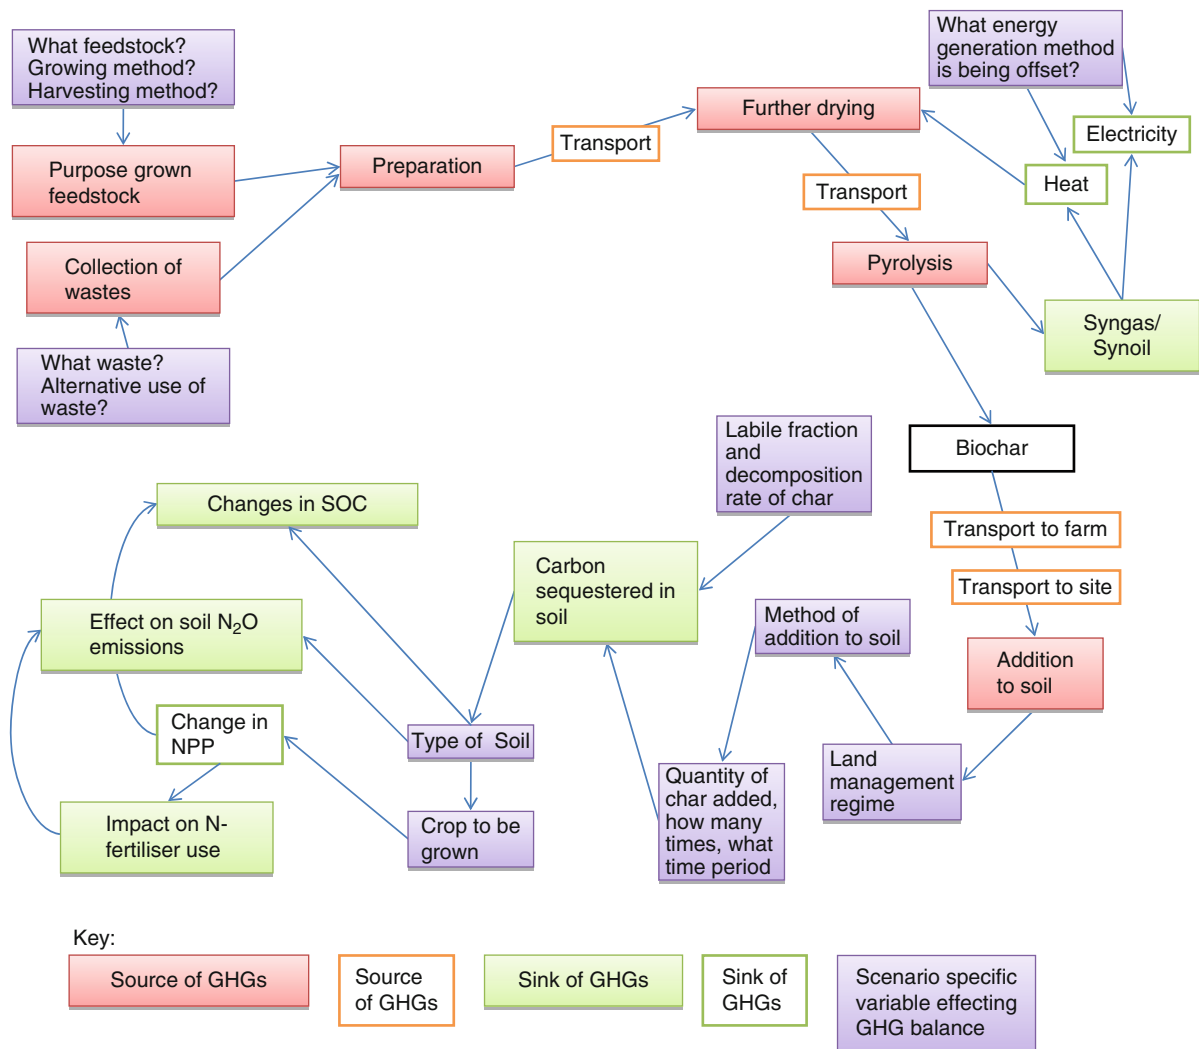

in each scenario, sustainability constraints have been met such that land upon which food is grown is not used for growing biomass for biochar production (i.e., only agri-residues and clean wastes are utilized) and indirect land-use change is not induced, incurring carbon-debt problems. Woolf et al. found that carbon abatement from use of biomass for biochar production was, on average, c. 20% higher than where the same

biomass is used for bioelectricity generation through combustion. The comparison depends however on the fossil fuel offset. Where coal is offset, then biomass combustion and pyrolysis-biochar have similar carbon abatement. The higher bioelectricity generation from use of combustion avoids more carbon emissions due to the high carbon intensity of coal (compared, say, to gas, nuclear, renewables, etc.). Pyrolysis-biochar performs better in terms of carbon mitigation, where offsetting is against a fuel with a lower carbon intensity because the energy penalty of pyrolysis is therefore less important (from a carbon point of view) (a point also made by [69]). A further issue explored by Woolf et al. is the potential role of soil fertility in influencing the carbon mitigation potential of biochar; namely, in areas of low soil fertility, biochar is anticipated to have greater agronomic benefit, increasing yields with the use of fewer inputs (and their associated greenhouse gas emissions). This means that, according to this analysis and in terms of carbon mitigation, biochar is most effective, where it is incorporated into poorer quality soils in regions where less carbon-intensive fuels are being displaced.

The IEA's Energy Technology Perspectives project has suggested that a reduction of $13 \text{ Gt C year}^{-1}$ is needed in 2050 relative to the “do-nothing” business-as-usual scenario [75]. If biochar could contribute 1 Gt C year^{-1} to “filling” this overall $13 \text{ Gt C year}^{-1}$, then its contribution would be roughly similar to the potential role of nuclear power expansion or enhanced power-generation efficiency and fuel switching.

The Carbon Abatement Efficiency of Pyrolysis-Biochar Systems

Carbon abatement efficiency (CAE) is defined as the net carbon abatement delivered for a given function unit (e.g., processing of a unit of feedstock, delivery of a kWh of electricity or heat, utilization of a given area of land, etc.). It is a way of comparing abatement efficiency between alternative uses of the same feedstock, land, or per unit of delivered energy. This is important in deciding how to use limited resources. The CAE is calculated from a life-cycle assessment (LCA) of the full PBS chain. An example of an LCA of a biochar system, including the impacts of biochar in the soil, is illustrated in Fig. 6.

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 6

A life-cycle system model for pyrolysis-biochar systems [55]

A number of LCA studies of PBS have been conducted for a range of different feedstocks, technologies, and agricultural contexts. The results are summarized in Table 6.

Table 6 shows that some studies present significantly higher net carbon-abatement values than others. For instance, Gaunt et al. [59] present values for switchgrass that are several times larger than those of Roberts et al. [56]. Their respective values are closer for corn stover (30% different). At first glance, the net carbon abatement for Miscanthus from Gaunt [59] and Hammond et al. [55] appear to agree, but not

when the results are compared with inclusion of the indirect effects of biochar in soil in the former study (in which case, the Gaunt et al. study has 60–100% greater net carbon abatement than the Hammond et al. study). While some results do appear to converge, the overall impression is of a wide range of different assumptions leading to a high degree of uncertainty. At present, it is not known which assumptions are most appropriate and in what context. For instance, the assumed CSF of studies in Table 6 varied from 0.68 to 1.0 (for a range of [not always specified] timescales). This difference alone can account for a 50% variation in net CA.

Biochar, Tool for Climate Change Mitigation and Soil Management. Table 6 Comparison of different life-cycle assessment studies of pyrolysis-biochar systems

Variable	Description	Gaunt and Lehmann [59]	Gaunt and Cowie [58]	McCarl et al. [76]	Roberts et al. [56]	Hammond et al. (2011) [55]	Ibarrola [57]

Variable	Description	Gaunt and Lehmann [59]	Gaunt and Cowie [58]	McCarl et al. [76]	Roberts et al. [56]	Hammond et al. (2011) [55]	Ibarrola [57]
Notes		1	2	3	4	5	6
Reference		Gaunt et al. [59]	Gaunt et al. [58]	McCarl et al. [76]	Roberts et al. [56]	Hammond et al. [55]	Ibarrola [57]

1. The CEF assumes 50% coal and gas, hence it is the average of the two values in Table 3 in Gaunt and Lehmann [59] converted from per hectare to per ton basis using the yield figures provided in the paper. The yield for corn stover is not given, so the CO₂na cannot be calculated.
2. The CEF assumes 50% coal and gas, hence it is the average of the two values in Table 18.2a ([58]). The first value shown does not include the application of biochar to crops or indirect effects of biochar upon soil incorporation. The value of these effects can be inferred to be from 0.2 (low), 0.66 (medium) and 1.14 (high) tCO₂eq.t⁻¹. The second value shown uses the medium values of the indirect effects and adds this quantity to the pyrolysis + fossil fuel offsets value. If the lower estimate of the indirect effects is used instead, the overall effect is reduced by c. 0.4 tCO₂eq.t⁻¹. In calculating the proportional contribution to total CA from the avoided fossil fuel emissions, stabilized carbon in char and the indirect impacts of biochar in soils, the medium value of the indirect effects have been assumed.
3. Lower value for switchgrass refers to slow pyrolysis; the higher value refers to fast pyrolysis.
4. For corn stover, the lower value is early stover and the higher value is late stover. In the case of the switchgrass, this does not take account of indirect land-use change (ILUC) arising from use of bioenergy crops. If ILUC is included, then the net carbon abatement is -0.036 tCO₂eq.t⁻¹ (i.e., an emission).
5. The value for wheat straw is the same as for barley and oilseed rape straw. Where large quantities of forestry residues are imported into the UK from Canada, the CO₂na is 1.08 tCO₂eq.t⁻¹. The value for short rotation coppice (SRC) is similar to the values for small round wood (1.15 tCO₂eq.t⁻¹).
6. Results for green waste, sewage sludge, and food waste are relative to incorporation of material in landfill sites with UK-levels of methane recovery. Values are also provided for incorporation of material into fast pyrolysis (10% char yield).

Different assumptions about useable or delivered energy from pyrolysis are also important contributors to the uncertainty. Some studies assume a much higher energy conversion efficiency than others, e.g., Gaunt and Lehmann assume a value that is substantially higher than conventional biomass combustion, and even gasification, suggesting that useable heat is also being utilized. Roberts et al. also assume effective use of heat from pyrolysis, hence use a high overall energy efficiency. Hammond, on the other hand, uses a more conservative value for net energy efficiency, which is substantially lower than straight combustion. How energy is treated in the LCA is important in making comparisons with CA from straight combustion or gasification since it is frequently assumed that heat is not readily used from such technologies where the principal purpose is electricity generation. Comparing net CA from PBS with delivered power and heat with biomass combustion with only power generation is probably not a fair comparison to make.

Some element of “biochar proponent optimism” has likely entered into the existing studies, and a more critical approach will be needed for the future. In summary, there is a moderate to high level of uncertainty attached to all existing values, and one should not pay too much attention to the precise numbers as they are very likely to change in the future as more understanding and experience is gained. The lack of reliable engineering data on the slow pyrolysis process at a commercial scale is one of the critical uncertainties. Most of the existing studies have used data from a single technology (BEST Energies, now Pacific Pyrolysis Pty. Ltd.), yet the results from this process have not been published in the peer-reviewed literature. This creates a potential weakness in the current argument in favor of biochar that needs to be addressed by acquisition of much better engineering data on slow pyrolysis.

Energy-Output to Energy-Input Ratios

The energy-output to -input ratio (also known as the energy yield) is the quantity of delivered energy (i.e., useable power and/or heat) divided by the quantity of energy required to produce that energy. Bioenergy systems typically utilize as fuels widely distributed biomass resources which require energy – frequently supplied by energy dense fossil fuels – to cut, prepare,

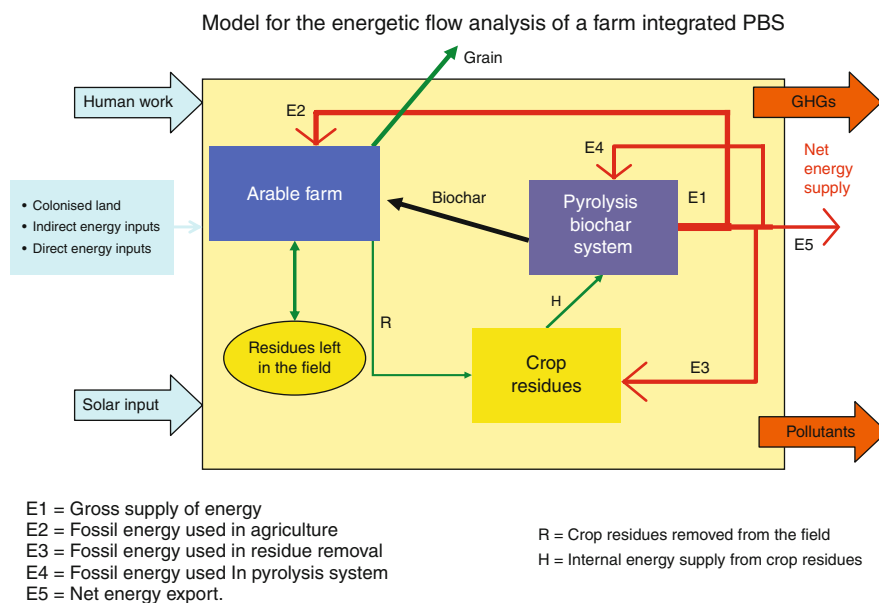

transport, store, process, and ignite feedstocks. Fossil fuel-derived energy is also required to manufacture, transport, and erect the equipment and infrastructure that is needed for the bioenergy system to function. In calculating the energy ratio, the energy content of the biomass itself is not included as an energy input since this is treated as “free energy,” having been derived from the sun’s energy through plant photosynthesis. The biochar energy system can be depicted as a set of inputs and outputs as in Fig. 7.

The energy ration in Fig. 7 is calculated as:

$$\text{Energy ratio} = \frac{\text{net energy output}}{\text{energy inputs}} = \frac{E5}{E2 + E3 + E4}$$

The use of highly dense energy sources (fossil fuels) to enable the utilization of very distributed bioenergy sources has to be carefully assessed to avoid the problems that have beset the production of bioethanol from maize in the USA. In that case, the energy output/energy input ratio (at between 0.7 and 2.2 MJ MJ⁻¹) is generally too low for the system as a whole to make energetic sense: what happens in effect is that the energy content of fossil fuels is being released to produce bioethanol with a similar energy content. The energy output/energy input ratio needs to be 2.0 or more for a bio-energy system to make energetic sense [77].

Several estimates of the energy-output/energy-input ratio of PBS are available, though due to the lack of reliable data on the pyrolysis process itself, especially at commercial scale, such estimates remain tentative. Gaunt et al. [59] provided a range of values that range from 2.3 to 7, depending upon the feedstock. However, Gaunt et al. use the gross energy output in calculating the energy yield, whereas the convention is to utilize the net energy output. The recalculated energy yield ranges in [59] from 1.3 (forage corn), 4.3 (switchgrass), 4.6 (miscanthus), to 5.9 (wheat straw and corn stover). The highest energy yields are associated with the use of crop residues (wheat straw and corn stover) since the energy inputs are lower for these feedstocks than for dedicated bioenergy crops (switchgrass and miscanthus). The study [59] assumes a biochar yield of c. 8.5–9%, with 38% of feedstock energy available as delivered energy. If a more modest net energy efficiency of 15% is assumed, however, then the energy yield is reduced to 1.1 (switchgrass), 1.2 (miscanthus), 0.1 (forage corn),

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 7

Pyrolysis-Biochar as an Energetic System (Jason Cook after Giampietro and Mayumi [77])

and 1.7 (wheat straw and corn stover). With a more conservative, and some would argue, more realistic assessment of the net energy efficiency, the energy yield falls below the critical value of 2 and is unlikely to make energetic sense.

Roberts et al. [56] provide values for the energy ratios of 2.8 for corn stover and 3.1 for switchgrass; however, as with Gaunt et al., this study makes highly optimistic assumptions regarding the net energy efficiency, using a value of 37%, requiring productive use of the heat from syngas combustion. Reliable and economic markets for heat from power plants are notoriously difficult to create, and much analysis avoids inclusion of heat in calculations of avoided fossil fuel emissions for this reason. It is therefore optimistic to assume effective markets for heat from pyrolysis plants, therefore. If the more conservative assumption is made that only electricity generation from pyrolysis at 15% efficiency will find an economically viable market, then the energy yields from Roberts et al. can be recalculated downward as follows: late stover from 5.5 to 1.65, early stover from 3 to 0.63, switchgrass from 5.5 to 1.65, and yard waste from 9.5 to 2.4. The energy yields turn out to be highly sensitive to the efficiency of the conversion process to delivered energy.

Assuming that Giampietro and Mayumi are correct in identifying 2 as a critical value for the energy yield for biofuels, below which the basic energetics of bioenergy systems cease to make sense, then it is apparent that pyrolysis-biochar systems need to be operating at net energy efficiencies of at least 20–30%, depending upon the individual feedstock and technology assumptions. Anything which increases the use of fossil fuels in the PBS (*ceteris paribus*) will also pose a challenge to the system energetics. Roberts et al. [56] report, for example, that an increase in transportation distance from the baseline (15 km) to 200 km reduces the net energy by 15%, while at 1,000 km, the net energy decreases by 79%. An 80% reduction implies an energy yield of 1 or below, but even a 15% reduction in net energy could bring the energy yield below 2.

More work on accurate calculation of energy yields is therefore urgently required. The most promising scenarios will be where forestry residues and other organic wastes are being utilized, i.e., where fossil fuel inputs to the provision of the feedstock are minimized (in the case of many wastes because some form of treatment is required in any case) and where long transportation distances are not required. The carbon-equivalent production emission for sawmill

residues in the UK is $4 \text{ kgCO}_2\text{odt}^{-1}$, while in the case of forestry residues, there is a negative emission of c. $50 \text{ kgCO}_2\text{odt}^{-1}$ as a consequence of avoided methane emissions from wood that otherwise decomposes [55]. UK arable straw entails a higher production emission of c. $200 \text{ kgCO}_2\text{odt}^{-1}$ (partly because c. 15% of the fossil fuels required for the arable crop production are allocated to the straw on economic grounds) [55]. This is actually greater than the production emissions of SRC and Miscanthus in UK conditions, where chemical fertilizers are not used (c. $20\text{--}40 \text{ kgCO}_2\text{odt}^{-1}$). Utilization of sewage sludge in SRC and Miscanthus results in higher N_2O emissions, though the sludge has to be disposed of in the baseline case so could arguably be ignored in LCA calculations.

It could be argued that if a key purpose of PBS is carbon abatement, critical values arising from energetic analysis are not necessarily relevant. This point may be valid, where the production of energy from the biomass is an ancillary benefit of a PBS development. For instance, the main purpose of a project may be the more effective disposal of an organic waste stream, and energy production a fortunate by-product and bonus: the waste would otherwise need to have been managed in some fashion. Yet, where the biomass has an alternative use as a fuel in co-firing, anaerobic digestion (AD), fermentation, dedicated biomass combustion or gasification, and where a market for such biomass and for bioenergy exists (e.g., whether with or without the aid of incentives), then an energetic analysis is appropriate to use. This is because a lower energy yield has to be compensated by increased energy production (or reduced demand) from some other part of the system.

Key Findings from Existing LCA Studies

Feedstock Suitability Hammond et al. [55] found that systems which utilize woody residue feedstocks tend to have the highest CAE, closely followed by purpose-grown woody feedstocks. Small-scale straw-based systems have a 15–30% lower CAE than wood residues, partly because of assumed scale-factors; the rest of the difference is explained by higher inputs for straw-based systems versus wood residues.

Roberts et al. [56] examined the impact of land-use change arising from the conversion of cropland from

annual crops to perennial switchgrass (direct change) and the subsequent need to convert land to cropland to replace lost agricultural land (indirect change). They included two estimates of the size of these direct and indirect land-use changes (886 and $406.8 \text{ kgCO}_2 \text{ t}^{-1}$ dry switchgrass). If the larger land emission value is used, then the overall CA of the PBS is negative (i.e., a positive emission of $36 \text{ kgCO}_2 \text{ t}^{-1}$), but is positive if the lower land-use-change value is used ($442 \text{ kgCO}_2 \text{ t}^{-1}$). Roberts et al. comment that PBS could conceivably *increase* net radiative forcing from GHG emissions if direct and indirect land-use-change emissions are associated with energy-crop establishment.

Ibarrola [57] found that biochar production from pyrolysis of wood waste (construction and demolition, plus commercial and industrial), garden and green waste, and food waste have greater CAE than sewage sludge or AD digestate (Fig. 8). This is because of the higher calorific value of the former, and the higher stabilized carbon content of their biochar product. Gaunt and Cowie [58] present a similar figure for CA

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 8

CA of PBS using different nonvirgin biomass feedstocks

of green waste compared to conventional landfill with CH₄ recovery (1.0–1.2 t CO₂eq.t⁻¹ oven dry feedstock). Joseph et al. [79] have recently presented more results for a range of nonvirgin biomass feedstocks in Australia, including poultry litter, paper sludge and green waste: the CA is between 1.4 and just over 2.0 t CO₂eq.t⁻¹ oven dry feedstock, the somewhat higher values being explained by the assumed waste-management baseline (which recovers less CH₄ emissions than is typical for many European countries).

Life-Cycle Stage Contributions to Carbon Abatement

Hammond et al. found that the largest contribution to CA is from stabilized carbon in biochar, accounting for approximately 40–50% of total CA. The next largest contribution is from the indirect impacts of biochar in the soil, all of which are currently uncertain: lower crop fertilizer requirement, lower soil N₂O emissions and increased SOC. These account for 25–40% of CA (the proportion changing with the size of other CA categories). The third major CA category in Hammond’s et al. study is fossil fuel offsets from renewable electricity generation at 10–25% of total CA. Similar information is presented in Fig. 9 in which the life-cycle stages of the UK lower resource supply scenario are broken-down to illustrate CO₂ emitting and abating stages.

In the Roberts et al. study, the proportion from stabilized carbon in the biochar is larger at 54–66%. The proportion from avoided fossil fuel emissions is also larger at between 26% and 40% depending on feedstock.

The main difference between Hammond et al. and Roberts et al. is that the former study assumes a higher value for the indirect soil impacts of biochar, principally due to the assumed accumulation of soil organic carbon as a consequence of biochar addition. As a consequence, the proportional contribution of stabilized carbon and avoided fossil fuel emissions is lower than in Roberts et al., which makes more conservative assumptions about the indirect impacts of biochar in soil. Of the studies reported in Table 6, the indirect impacts of biochar in soils upon net carbon abatement tend to be smaller than assumed in Hammond et al., although Gaunt and Downie assume even higher values. Ibarrola’s study presents a similar contribution breakdown as Roberts: the largest contribution to CA for both fast and slow pyrolysis in the case of wood, food, and green wastes is carbon stabilized in biochar (45–55%, excluding use of digestate case). The second largest contribution comes from offset GHG emissions from fossil fuel emissions (20–30%). Where the assumed indirect impacts are lower, then the contribution of stabilized carbon and avoided fossil fuel emissions are

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 9
CO₂eq abatement by life-cycle stage for lower biomass supply scenario (UK conditions)

proportionally higher. The studies in Table 6 indicate that transport emissions are a relatively minor contribution to overall lifecycle emissions (several percent for biomass and biochar movement of c. 20 km each).

CO₂ Equivalent Emissions Per Unit Delivered Energy

Hammond et al. presents a carbon abatement for PBS of 1,500–2,000 kg CO₂eq MWh⁻¹ (1.5–2.0 kg kWh⁻¹) for large systems, compared to a UK CEF of 0.56 kgCO₂kWh⁻¹ in 2006 [53]. For comparison, modern bioenergy systems (combustion with grate or fluidized bed, gasification) produce emissions from between 0.03 and 0.07 kg CO₂ kWh⁻¹ [80], or from 0.05 to 0.30 kg CO₂ kWh⁻¹ according to the Environment Agency [81]. While PBS appears to offer far better CA MWh⁻¹ than conventional bioelectricity, this is a somewhat misleading finding. Much of the CA from PBS results from stabilized carbon in the biochar and from indirect soil effects (rather than from offset fossil fuel emissions), while the denominator – electricity generation per unit biomass – is lower than for conventional bioelectricity due to lower efficiency. Thus, the CA per unit electricity is high, but electrical efficiency is low.

CO₂ Equivalent Emissions Per Hectare

On an area basis in the UK, Hammond et al. found that CA ranges from seven to nearly 30 tCO₂eq ha⁻¹ year⁻¹, depending on PBS feedstock (Fig. 9). Waste feedstocks such as arboricultural arisings are the most efficient in terms of land use as they do not require any additional land use change and do not interfere with crop-production systems; moreover, they are commonly disposed of as wastes and hence PBS incurs less emissions through additional transport, handling, and storage stages. Such numbers compare favorably with conventional bioenergy in the UK, which abate between 1 and 7 tCO₂eq ha⁻¹ year⁻¹; the most productive biofuel system in the world – bioethanol from sugar cane in Brazil – abates c. 16 tCO₂eq ha⁻¹ year⁻¹, so biochar performs well under this metric (Fig. 10).

Delivered Energy Generation from Pyrolysis-Biochar Systems Versus Combustion

Roberts et al. compared use of biochar for soil with use of biochar to replace coal and found that biochar to soil resulted in 29% more carbon

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 10

Annual CO₂eq abatement per hectare for UK conditions. No value is given for sawmill residues or arboricultural arisings since the plants are not grown specifically for pyrolyzable residues

abatement (627 vs 864 kgCO₂eq t⁻¹). A more realistic comparison is between PBS and direct biomass combustion and, in this case, Roberts et al. found that carbon abatement was actually less for PBS than for combustion (987 vs 864 kgCO₂eq t⁻¹) (using a CEF for natural gas). On the other hand, approximately half of the CA from PBS involves removal of CO₂ from atmosphere, compared to biomass combustion, where all the carbon abatement arises from avoided fossil fuel emissions.

In Hammond's et al. study, PBS performs somewhat better compared to combustion than in Roberts et al., partly reflecting somewhat higher CA per ton feedstock in the former than in the latter. The comparison depends upon the relative energy efficiencies of the two processes and upon the CEF used to calculate avoided fossil fuel emissions. For example, at an efficiency of 15% and with a CSF of 0.68, PBS appear to offer greater CA than combustion at 33% efficiency (using an average UK grid CEF) even without inclusion of indirect soil effects, but cannot compete with combustion (or gasification) at an efficiency over 40%. In systems co-firing biomass with coal, efficiency can be significantly higher in new plants (up to 42%). Hence, either the indirect benefits of biochar upon net GHG emission fluxes would need to be on the scale proposed in Hammond or else the efficiency of the PBS would need to increase (or some combination of the two). Where biomass co-firing is combined with CO₂ capture and geological storage (Bioenergy CCS, or BECCs), PBS is not able to compete in terms of carbon abatement (because the CCS process captures c. 90% of the carbon in the feedstock compared to c. 50% of feedstock carbon conserved during pyrolysis).

If grid average of 80 kg CO₂eq MWh⁻¹ is attained by 2030 (which is required in the UK context if the government's carbon-reduction targets of an 80% reduction by 2050 relative to 1990 levels are to be met) and assuming biomass is still available as a resource, biomass combustion offers almost no carbon abatement benefit [82]. PBS meanwhile still offers CA benefits, i.e., it has net negative CO₂eq MWh⁻¹ emissions. Yet, as noted above, at current net energy efficiencies, PBS is unlikely to be the technology of choice for generating electricity so it may have a rather limited role.

From the results of Roberts et al. and Hammond et al., it is evident that PBS is not necessarily more efficient in terms of CA than other bioenergy options: it will depend on the detailed analysis of each individual case. It is clear in general that conversion of the energy in feedstock into useful delivered energy (heat and power) will have to be reasonably efficient (20–30%) for PBS to compete on any scale with direct combustion. In the longer-term perspective, however, PBS may become more valuable (compared to combustion technology) due to its ability to actually remove carbon from the atmosphere. Exactly when this benefit would be realized is highly uncertain and context-dependent (e.g., reliant upon the outcome of other highly uncertain processes).

Sensitivity Analysis

Hammond et al. found that the following variables were all important in influencing the overall net carbon abatement: total handling losses, char yield, total electrical efficiency, use of heat, soil organic carbon accumulation, the allocation of GHG emissions to the production of the feedstock, fraction of labile carbon and – most importantly – the Mean Residence Time (MRT). If the MRT is below 500 years, there is a reduction in the CAE which begins to look concerning, although this partly depends on the time horizon over which an analysis is undertaken. Hammond found low sensitivity to the following variables: distance travelled (biomass and biochar) (up to 200 km), reduced nitrogen fertilizer application (0–50%), and reduced nitrous oxide emissions (0–100%).

In their LCA, Roberts et al. identified broadly similar sensitivities to Hammond et al. The results were sensitive to: emissions entailed in feedstock collection, stability of the carbon, biochar yield, and syngas yield. There was a lack of sensitivity to N₂O emission suppression and to distance travelled (except where this was 500 km +). Needless to say, the results of any such LCA are sensitive to the assumed CEF of the fossil fuel which is offset.

There are large uncertainties associated with the LCA work presented here. Biomass production systems vary in space and with time, making a calculation using a single number problematic. For the nonvirgin waste feedstocks, considerable uncertainties occur with

respect to the management of individual landfill sites (e.g., the biodegradable fraction, oxidation factors, CH₄ recovery, etc.), making comparison of PBS to existing options difficult.

How Cost-Effective Are Pyrolysis-Biochar Systems?

Gaunt and Lehmann [59] calculated that the cost of reducing a ton of CO₂ in the PBS they examined was between \$9 and \$16 compared to utilizing the same char as a fuel. Since they did not undertake a full economic costing, this figure does not allow comparison with other marginal abatement carbon costs (MACCs).

McCarl et al. [76] undertook a full economic costing and found that the net present value of the PBS examined (70 ktpa corn stover, mid-west USA conditions) was $-\$70 \text{ t}^{-1}$ feedstock for slow pyrolysis and $-\$45 \text{ t}^{-1}$ for fast pyrolysis, i.e., it is a loss-making venture under these assumptions. This assumed a carbon value of $\$4 \text{ tCO}_2^{-1}$ abatement and an agronomic value of $\$33 \text{ t}^{-1}$ biochar or $\$11.5 \text{ t}^{-1}$ feedstock. The biochar production cost (i.e., ignoring revenues from biochar as a form of carbon storage or arising from its agronomic value) is therefore approximately $\$85 \text{ t}^{-1}$ feedstock or c. $\$240 \text{ t}^{-1}$ biochar. The “energy penalty” cost of utilizing char as a soil amendment rather than as a fuel is $\$40 \text{ tCO}_2^{-1}$, considerably higher than Gaunt and Lehmann’s estimate of $\$15 \text{ tCO}_2^{-1}$, though similar to other estimates (e.g., Lehmann [9]).

Roberts et al. [56] present data on net present value of their USA-based PBS (c. 50 ktpa) which appears to indicate some positive NPVs. This is as a consequence of a very high carbon-price assumption ($\$80 \text{ tCO}_2^{-1}$). Even their “low” carbon price ($\$20 \text{ tCO}_2^{-1}$) is actually higher than the 2008–2010 EU ETS market value of $\$10\text{--}20 \text{ tCO}_2^{-1}$. If we remove the carbon revenue from the calculation along with the small benefit in increased fertilizer efficiency (but retaining the value of the P and K nutrients in the char), the NPVs are all negative. The production costs, expressed per ton of biochar, are: $\$155 \text{ t}^{-1}$ for late stover, $\$124\text{--}142 \text{ t}^{-1}$ for switchgrass, and $\$13 \text{ t}^{-1}$ for yard waste. These costs are lower than McCarl et al. [76], but not much so (40% or so lower). The exception is for yard waste in which case the cost of production is much lower due to the revenue gained through tipping fees and the other avoided costs of organic waste management.

Shackley et al. [158] present economic data on the situation in the UK for a range of feedstocks, with three plant sizes (small: 2 ktpa; medium: 16 ktpa; large: 184 ktpa). They provide a range of values of the costs of biochar production from $-\$220$ to $\$580 \text{ t}^{-1}$. The negative values arise from waste feedstocks, where there is a revenue stream from tipping fees which can otherwise be large in the UK context. The production costs are typically lower for the large-scale pyrolysis units due to lower capital, operational, and maintenance costs per unit production. The costs also vary depending upon the assumed storage option. For the virgin feedstocks, production costs are closer to McCarl et al. than to the Roberts et al. estimate above.

Brown et al. [161] compared the internal rate of return (IRR) for slow and fast pyrolysis assuming an increasing carbon price to 2030, use of gas co-product for heating and bio-oil refined to gasoline (in the case of fast pyrolysis only). The projected IRR for slow pyrolysis is negative out to 2030 for feedstock costing $\$83$ per ton. A zero cost feedstock would deliver an IRR of between 8% and 17%, but this is not considered sufficiently profitable for investment in a new technology. Brown et al. [161] found that the profitability of both slow and fast pyrolysis depended primarily upon the value of the energy product(s). Yoder et al. [162] develop a product transformation curve using optimisation and econometric analysis of existing data for quantifying the trade-off in pyrolysis between bio-oil and biochar production.

As for the LCA, costs are typically context-specific, and there are some niche applications where the NPV will be more evidently favorable, e.g., where a type of biochar has a high agronomic or soil-related value. A further example is where the biochar is a “waste” product from an economically viable energy project (Box 3).

To summarize, the economic viability of biochar production and application are currently highly uncertain. Feedstocks – especially clean ones – are frequently expensive in developed countries and increasingly in demand by other users such as for Anaerobic Digestion, composting, combustion, gasification, and so on. Technology costs associated with pyrolysis are especially hard to predict at the present time, and most estimates in the literature are based upon one or a few designs. At present, the incentives structure in most

Box 3: Gasification of Rice Husks: Case Study from Cambodia

Rice husks are gasified in an Ankur gasifier to produce syngas that is fed into an engine that powers a rice mill. The system is economically viable (due to mill being off-grid, hence otherwise having to rely upon expensive diesel fuel for power generation). Carbonized rice husks (CRHs) are the waste product, which accumulate, and can become an environmental problem. The CRH yield is c. 30%, and the carbon content of the char is c. 35%. Therefore, for each ton of rice husk, 300 kg of CRHs are produced containing 105 kgC or 385 kgCO₂. The labile C content is <1% and the CSF is 0.92 hence the stabilized carbon content is c. 350 kgCO₂t⁻¹ biochar. The cost of application to agricultural fields in Cambodia is low – estimated at \$1t⁻¹, while the agronomic value (based upon unpublished research) appears to be c. \$2 to 8 t⁻¹. Since the CRHs are (currently) free, the value of the biochar is c. \$1 to 7 t⁻¹; this is an important potential source of additional income in a subsistence farming system such as Cambodia.

If the rice husks were otherwise disposed of in irrigated paddy, there is also the value of avoided methane emissions from gasification. For every 1 t of applied rice husks, 40 kg of carbon is converted into 53 kg of methane, equivalent to 1,219 kg CO₂.

If the stabilized carbon can have a value, say at \$5 t⁻¹ CO₂, then the additional value of the CRHs is \$1.6 t⁻¹ biochar. Adding to the agronomic value, the overall value is between \$3 and 8 t⁻¹ biochar. And if the CA value of the avoided CH₄ emission is included, this would further rise to about \$9–14 t⁻¹ biochar. Clearly, if the CRHs do indeed have a demonstrable and predictable agronomic value, demand for its use may increase, and the producer may begin to sell the CRHs rather than give it away free as a waste product.

countries is focused upon renewable electricity generation, and there is no mechanism for rewarding stabilized carbon abatement in the soil. If carbon abatement is the primary policy driver, inclusion of stabilized carbon in biochar and its indirect impacts on soil GHG fluxes would need to be given some value alongside renewable electricity generation. One problem with carbon-based land crediting is that it raises the

issue of how to establish a baseline, and many current land-owners and occupiers, e.g., farmers, are reluctant to begin to establish inventories of carbon-equivalent fluxes over their land (such as might be required to establish a baseline against which a biochar project could be assessed). Some countries, e.g., in Europe, have previously expressed their skepticism at including land-based carbon crediting as a major carbon-abatement strategy within the UNFCCC. Scientific uncertainties and technical challenges surrounding monitoring, verification, accounting, and reporting (MVAR) in relation to biochar additions will mean that developing a robust methodology for inclusion of biochar in carbon markets (voluntary or through the Clean Development Mechanism) will be challenging until scientific knowledge improves.

Where biochar is potentially more economically viable is where it is able to treat wastes that incur high tipping fees to landfills. In those situations, PBS may be a cheaper disposal route than landfill or incineration. Whether the char produced can be used in agricultural soils remains uncertain due to the risk of contamination. At present, there is a lack of a clear risk assessment and regulation pathway for such substances. A further situation where biochar might already be economically viable is the case of gasification char – which is a waste product of a financially solvent energy generation technology. If this char can be shown to be beneficial to soils and to avoid introducing contamination, then it could be financially viable to distribute such material to agricultural systems.

What Are the Impacts of Biochar on Soil?

In this section, we turn to the question of the impacts of biochar on soil. A summary of the published literature has been presented previously [6, 7]. Much of the evidence comes from the study of charcoal in the natural environment: this provides the only source of relevant direct evidence for long-term stability of biochar, having been used historically by humans or as a result of deposition after periodic fires in many natural ecosystems. Given the similar formation and chemical characteristics, charcoal in the natural environment provides a powerful tool to investigate the long-term stability of biochar. However, the short-term impacts of biochar may not be well represented in studies of old charcoal.

This is in part because the feedstock can be quite different, and partly because the more complex composition of biochar is overlooked. Also, any labile components associated with the charcoal will have been mineralized prior to sampling.

The more temporary beneficial impacts of biochar may be chemical and result from leachable ash and modification of soil pH, promotion of short-term microbial activity, including the effect of small labile fractions. Physical benefits may arise from modification of soil bulk density, water holding capacity, and promotion of soil aggregation (possibly in combination with soil biological effects). These effects may be temporary or long term. Thermal properties may change as well [83].

Other effects relate to the provision of cation exchange capacity (CEC) and specific surface area (SSA), biological associations (with micro-organisms, fungi, and with plant roots), and bio-physical benefits (mediating the connection of micro-organisms and microbial substrate, promotion of mesofaunal activity, including earthworms). The potential for detrimental effects on the soil would depend on the source of the biochar applied, and the rate and timing of its application. Negative impacts could include leaching of nutrients, addition of toxic elements (metals), or the introduction of organic contaminants. Where biochar has a high affinity for nitrogen, there may be negative short-term effects on crop nutrient supply, i.e., potentially reducing nitrogen availability to the plant in the period after application [84].

Scientific research of biochar is a relatively new topic, and therefore generality in site-specific observations is not yet apparent, while extrapolation from individual observations is not yet possible. At this point, a convergence in methodologies has not emerged and until recently, there have been no strategic research programs to provide a systematic evaluation. The nature of PBS also demands coordination and consolidation of research efforts with pyrolysis engineering in order to produce selected biochar that expresses particular and possibly multiple beneficial functions in soil.

Key Functions of Biochar

Provision of Labile Organic Carbon Rapid utilization of labile substrates in soil can build a store of

nutrients in soil microbial biomass, which may become available for plant acquisition and growth over time. The potential benefits of labile carbon in soil can create a constraint to crop growth if substrate nitrogen is low, and if at the time of addition inorganic (i.e., available) nitrogen in the wider soil is limited. This is because nitrogen as well as carbon is required to build new biomass, and microbes will out-compete roots.

Nitrogen is progressively volatilized during pyrolysis so the ratio of carbon to nitrogen in biochar is generally much higher than in the feedstock. However, if biochar is entirely stable, it will not present the readily accessible carbon substrate necessary to create microbial demand for external nitrogen. Whether significant nitrogen immobilization of soil nitrogen occurs should therefore depend on the size of the biochar addition, the size of the labile fraction, and whether the ratio of nitrogen to carbon of the labile fraction reflects that of the bulk biochar sample.

Storage of Stable Carbon The stable portion of biochar is the fraction for which, in the future, a carbon credit might be claimed and, for the purpose of climate-change mitigation, may be the component that remains in the soil for at least 100 years [7]. There is, as yet, no robust methodology for establishing the MRT of a specific biochar product: this is one of the key scientific uncertainties and policy needs. The sum of stable and labile carbon should not reflect the total carbon content of biochar as fractions of intermediate stability are also likely to be present.

Supply of Plant Available Nutrients Aside from nitrogen, most potential nutrients in pyrolysis feedstock are largely conserved during pyrolysis (as also are potentially toxic elements). Progressive elimination of carbon, oxygen, and hydrogen during pyrolysis therefore increases the total concentration of minerals in the char residue, and in potentially extractable forms as ash. Biochar ash content increases in inverse proportion to retained carbon feedstock, analogous to that which arises during combustion but distributed within a complex physical matrix.

Solubilization of ash may result in minerals becoming available to plants on addition to soil, although since phosphorus (as phosphate) is rapidly complexed with minerals in soil, this may depend on scavenging

directly from char by roots or symbiotic mycorrhizal fungi. In general, introduction of readily available crop nutrients can promote mineralization of organic matter, especially in marginal environments.

However, porosity, and more specifically pore connectivity, may control the release of soluble nutrients from char, making release progressive rather than instantaneous as may be the case in the solubilization of combustion ash. This process could be associated with the mineralization of condensed tars and oils that appear to block biochar pores [85].

Modification of Soil pH The typically alkaline nature of biochar may increase microbial activity in acidic soils by increasing pH and with this, another potential source of “priming” for the decomposition of pre-existing organic matter, although modification of soil pH may also increase plant productivity and thus the amount of carbon substrate added to the soil through roots and residues. Mass for mass, the value of char in pH modification may be up to one third that of agricultural lime [86] and at experimental rates can increase soil pH by 1 unit.

Modification of Soil Physical Characteristics

Depending on the distribution of particle size in the soil, the rate and nature of biochar applied and the time since application, soil pore-size distribution and water holding capacity may be affected. Porosity in char may occur at a range of scales, which affects the proportion of water that can be retained, and equally the accessibility of held water and solutes to plants which can exert sufficient tension to extract the contents of macropores (0.1–30 μm diam) that may not drain naturally. Structurally sound pores of this dimension are abundant in fresh wood-derived charcoal [87], and the connectivity of the relatively small number of larger pores has been investigated in three dimensions by tomography [88].

However, the fresh particle size of powdery charcoal created from grass feedstocks appears to be less than 50 μm [89], and weathered charcoal, while generally found in larger fragments, also resides in this size range [90]. In clayey soils, particles may be less than 5 μm [91]. During weathering, and particularly for char from woody substrate, the position of char fragments within the soil mineral matrix is likely to alter over time. The

effect that this has on total porosity, accessible pores, and accessible surface areas has not been explicitly examined.

Nonetheless, while initially macroporous, it is established that the great majority of total porosity in wood-derived charcoal may reside in micropores of nanometer size [92]. Oils and tars could represent less stable components of biochar around which microbial activity could promote micro-aggregation, relevant to water infiltration and resistance to water erosion. An apparent role for charcoal in aggregation has been observed in field soils [90], although short-term incubation with activated charcoal did not cause aggregation under controlled conditions [93].

Cation Exchange Capacity and Sorption Progressive abiotic and biotic surface oxidation of charcoal results in surface proliferation of carboxyl groups and an increasing ability to sorb cations [33, 34], explaining high cation exchange in archaeological soils [35]. Negative charge provides the possibility for reversible storage of available nitrogen (ammonium, NH_4^+) relevant to soil-based N_2O emissions and nitrate leaching. A mechanism based on the dehydration of phosphate and charcoal has also been described for the adsorption of phosphorus [94], which may explain the apparent impact of biochar on crop phosphorus uptake, possibly aided by arbuscular mycorrhizal fungi [95].

Charcoal has the capacity to sorb polar compounds, including many environmental contaminants [96], particularly PAHs for which it may be the dominant sink in soils and sediments [97]. The significance of biochar addition in removing contaminants from the environment depends on its capacity to fulfill this function relative to charcoal, the affinity (security and reversibility) of stabilization, and the ultimate fate of both char and contaminants [164].

Microbial Activity The possibility that biochar catalyses breakdown of organic matter by providing microbial habitat alone is improbable since sustainable microbial proliferation depends on a renewable source of accessible carbon substrate as well as nutrients. Provided that the majority of biochar carbon is highly stable, after an initial flush of mineralization, microbes that inhabit biochar pores will depend primarily on the indirect effects of biochar to obtain an enhanced supply

of substrate. This could either be through the capture and retention of soluble organic matter otherwise lost to deeper horizons or watercourses, or through a change in loci of plant root activity. Increased plant productivity however should be reflected in increased exudation of carbon through roots, and the deposition of carbon from residues of above-ground growth. The complication that this adds to interpretation of field data has been highlighted by Major et al. [98].

Many plants can form symbiotic associations with mycorrhizal fungi, whose filamentous hyphae provide an extension to plant roots which can enhance acquisition of both nutrients and water, at the expense of some host plant carbon. Although potentially limited by inoculum, soil-chemical conditions and the abundance of exploitable nutrients are more likely to limit mycorrhizal proliferation in most circumstances. Reported promotion of mycorrhizal activity by biochar [99, 100] could reflect utilization of reversible stores of water and soluble nutrients, or exhaustible “mining” of nutrients embedded in ash. Warnock et al. [101] proposed a range of possible mechanisms.

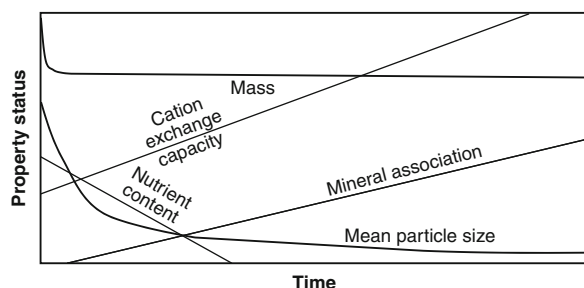

Limitations of Existing Research Base Until recently, there have been no directed research programs to strategically evaluate biochar for its function in soil. Much of the current understanding of the function of biochar rests on published data for charcoal, often in the context of natural systems and wildfire. For reasons highlighted in sections “[Biochar Production](#)” and “[Properties of Biochar](#),” the function of biochar in soil is strongly influenced by feedstock and formation conditions, and charcoal may only provide an insight into some general principles of biochar function in soil. In addition to the problem of extrapolating from studies of charcoal, pilot- and commercial-scale pyrolysis may produce biochar that differs from the products of bench-scale pyrolysis systems operating under ostensibly the same conditions. There is no existing research to evaluate char from gasification, which is likely to provide a function between that of biochar and ash from straight combustion.

Categorization of Current Literature

- *Sediment or soil:* Early evidence for the stability of biochar arose from sediment studies, where

charcoal is preserved under anoxic conditions in which decomposition proceeds inherently slowly [102, 103].

- *Static or dynamic:* Static studies provide snapshot comparisons for a response variable at locations where a relevant soil (or other) variable differs, e.g., presence or absence of vegetation burning history [104, 105]. In a dynamic experiment, a “treatment” is imposed, and change in response variables over a time period determined, or ideally its trajectory observed through intermediate measurement. Chronosequence studies are a variant of the latter that enable long-term dynamics to be studied using samples deemed comparable, aside from the point in history at which the (ideally singular) change or intervention occurred [106–108].
- *Biochar or charcoal:* Natural fire contains an anoxic zone, where biomass pyrolysis prevails over combustion. Natural fire yields low charcoal conversion rates in the range 0.1–5% [109]. Wildfire is typically brief and the peak temperature variable. With rapid heating rates, the conversion may be partial, superficial, or progressive and affected by vegetation moisture content. Wildfire and charcoal are significant considerations in the global carbon cycle, and now an established topic for research.
- Much work on the dynamics of charcoal has been undertaken in this context, and laboratory studies have aimed to mimic wildfire carbonization by exposing biomass to similarly brief, variable, but generally low (ca. 350°C) temperature and semi-oxic conditions, i.e., limited or partial restriction of air flow. Experiments with char produced with complete exclusion of oxygen are much more limited and recent. Published research using char from commercial pyrolysis reactors rather than material produced in a laboratory-scale batch process are very scarce. Only eight studies categorized in [7] used pyrolysis char.
- *Short term or long term:* The various functions of biochar (Fig. 11) may be manifest over different timescales and, crucially, the trajectory of these functions appears to be nonlinear and may not be entirely independent of other functions or the wider system. The average duration of the dynamic studies identified in one literature review [7],

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 11

Schematic to illustrate the challenge of unraveling multiple functions of biochar whose possible trajectories strongly differ

including those undertaken in field plots (but excluding long-term chronosequences), was 11 months. Although the chronosequence approach has been employed to observe the development or demise of functions that change slowly over time (rather than emerge or decline rapidly at the start), few attempts have been made to short cut such change, other than by imposing favorable laboratory-imposed conditions.

- *Gasification or fast or slow pyrolysis:* After oven-drying, plant biomass usually contains about 45% carbon by mass, and a few per cent mineral ash. Ash is broadly conserved, but the proportion of carbon that is retained is specific to the process. Combustion leaves trace amounts of carbon, gasification less than 10%, and pyrolysis typically 30–40%. Ash includes key mineral nutrients such as phosphorus and potassium, other metals and a range of micronutrients concentrated by loss of total feedstock mass in the conversion process [110]. The nutrient value of the products differs markedly on a carbon-mass basis, but in terms of their value to crops will depend not only on rate of char application but on the physical accessibility of nutrients in the char to leaching, plant roots, and mycorrhizal fungi. The production process and feedstock mineral content will also modify the pH of the char by-products, which tend to be moderately to highly alkaline.
- *Feedstock:* Scanning electron microscopy of fresh charcoal and charcoal aged in the natural environment reveals a cellular structure resembling that of

the woody feedstock from which it was derived, e.g., lignified cell walls of dead xylem cells. The structure of char from grass and nonwoody plant material is rarely reported and, similarly, nor is the structure of char produced from digested or composted materials.

- *Tropical or temperate:* Under otherwise equal conditions (moisture, nutrient, and substrate availability), biological activity increases with temperature. Consequently, soils in the tropics tend to be depleted in organic matter and associated biological activity relative to those from temperate regions. In addition, soils that are very old have usually been subjected to extensive weathering and leaching and display low-inherent fertility and are often acidic. Although all functions of biochar may be expressed at all locations, some will be more conspicuous in such soil. In field studies and controlled experiments, half of the research effort has been undertaken in regions with above 20°C mean annual air temperature, and only one fifth in temperate zones below 10°C.
- *Laboratory or field:* Laboratory conditions enable variables and functional attributes to be isolated or controlled, and the impact of climatic variation to be removed. Permutations of different factors are possible since the space and resource requirement may be relatively small and good replication is possible. The interactions between functional attributes of soil and biochar with the wider environment, such as fluctuations in rainfall and evaporation impacting leaching, soil structure, and microbial community composition, can only be assessed in the field. However, the rate at which processes proceed in the field is dictated by the ambient climate and cannot be manipulated. Spatial heterogeneity demands intensive sampling which can constrain experimental design.
- *Soil or soil with plants:* Plants provide a sink for soil nutrients, exert suction on soil pores, and secrete compounds and enzymes that mobilize nutrients and modify soil surfaces. The microbial activity that concentrates around plant roots may “prime” processes that would not otherwise occur, for example, the co-mineralization of recalcitrant biochar and labile glucose [111]. However, the complex soil environment does not comprise such discrete

components and plant-derived substrates are separated by the soil mineral matrix.

- *Empirical (descriptive) or mechanistic (predictive)*: Empirical studies identify statistical relationships between two or more test variables; mechanistic studies seek to understand the reason for such relationships. Mechanistic approaches should offer greater prospect for prediction of effects at other locations, being based on a fundamental understanding of the underlying process. Although technically more robust, mechanistic understanding may take time to acquire and still not be accurate; both approaches require considerable validation especially where multiple variables or processes are involved (Fig. 11).

Extrapolation from Studies of Environmental Charcoal

Given the basic similarity in formation and the relatively abundant literature, it is necessary to view biochar in the context of the existing understanding of charcoal, especially in terms of long-term stability. To date, however, studies that compare char produced under a range of conditions, e.g., varying levels of oxygen exclusion, in terms of agronomy, mineralization, or other parameters relevant to biochar deployment, are lacking. Until these studies have been completed, the congruence in the properties of these materials remains uncertain.

Does charcoal in soil constitute soil organic matter? In the discrimination of more and less recalcitrant forms of organic matter in soil generally, the ratio of oxygen to carbon broadly decreases with age with progressive removal of oxygen through biological or chemical “oxidation.” Charcoal has a characteristically low O:C ratio, while graphitic black carbon (the most stable form derived in combustion) is essentially elemental carbon [112]. By comparison, charcoal and biochar are merely highly depleted in oxygen and hydrogen, containing groups that are strictly organic (most particularly aromatic forms), and part of the soil organic carbon pool.

Can charcoal be distinguished from other soil organic matter? Charcoal is particularly abundant in aromatic carbon that occupies a distinct position in the nuclear magnetic resonance spectrum for carbon (^{13}C NMR), displays a minor depletion in the abundance of the

scarce carbon isotope (^{13}C) relative to other compounds, and is characterized by certain biomarkers (so far, benzene polycarboxylic acid and levoglucosan have been most extensively evaluated). Charcoal is partially resistant to some chemical oxidants typically used to quantify total soil carbon (potassium dichromate), and both chemical and photo-oxidation have therefore been used to quantify it. However, none of these signals have proven entirely exclusive, and the procedures for measurement are complex or slow. Because the functionally relevant level of stability is itself ill-defined or context specific, the analytical separation of charcoal and “ordinary” soil organic matter has yet to be perfected.

What is the historic significance of charcoal in the global carbon cycle? Models describing soil carbon in the agronomic or global change context consider a near-inert soil-carbon fraction to correctly simulate response to altered climate or organic matter inputs, which being site-specific generally reflect, at least in part, contrasting abundance of charcoal in regions where wildfire is more or less frequent. The rate, extent, and completeness of conversion of biomass to charcoal in wildfire is highly variable. Nonetheless, making assumptions about such factors based on available evidence leads to estimates for a mean residence exceeding 1,000 years [113]. Charcoal is thought to account for 1–20% of organic carbon in soils, and at least 150 GtC of the global soil pool comprises charcoal or its more condensed or graphitic relatives, soot and elemental black carbon [11]. This implies that up to 150 Mt of carbon has annually cycled through the biosphere in the formation and degradation of charcoal-derived carbon.

Are the impacts of biochar carbon analogous to those of soil organic matter? Some properties of biochar, and specifically its impacts on physical soil properties, are also associated with bulk soil organic matter. It is not, however, safe to assume that the mechanisms by which these are provided are identical, or that the impacts are equivalent in magnitude, direction, or duration – and thus that biochar can provide a direct substitute for higher levels of other organic matter in soil. This is of practical importance since biochar is carbonaceous and thus not readily distinguished from organic matter using current techniques. This is analogous to the challenge of discriminating chalk and limestone from organic carbon in soil.

Can impacts be predicted from ex situ properties? The ex situ characteristics of organic matter and biochar are unlikely to be additive with respect to a soil's properties. For example, certain soil minerals (clays) have a high cation exchange capacity; although organic matter has higher specific exchange capacity mass for mass, binding between organic and mineral fractions shields exchange sites at the molecular-scale and reduces the sum effect. At the moment, it is not completely clear whether interactions between char and mineral particles will occur significantly at this physical scale or primarily as discrete, disparate particles. Cation exchange capacity of biochar also appears to evolve over time, and it is likely that many other properties have a trajectory which is currently ill-defined.

Evidence to Address Key Questions around PBS

Biochar and Contaminants In terms of human health and the food chain, the irreversibility of biochar addition is a key consideration. Existing soil amendments contain immobile components, albeit in less visible form and biochar inherits the potential risk posed by the feedstock that might otherwise be directly applied (see section “[Properties of Biochar](#)”). However, the class of these compounds known to be formed in the charring process itself (polycyclic aromatic hydrocarbons, PAHs) is process dependent. Without extensive evaluation of pyrolysis char, it is difficult to assess the risk posed by PAHs in PBS specifically as most data available relates to charcoal.

Charcoal is generally produced at lower temperatures that might favor PAH formation, but vapors may combust rather than condense and could thus be eliminated. Levels of extractable PAHs in charcoal are variable, but reported concentrations [114–117] generally fall between those reported for urban and rural soil on a mass basis (see [Table 2](#)). These compounds are persistent but ultimately degradable in soil [50].

The effect of association with chars on rate of degradation of PAHs, and the balance between rates of accumulation and release has not been systematically addressed. Concentrations of PAHs in soils subjected to natural fire suggest, however, that degradation is in excess of sorption. The capacity of both activated and nonactivated charcoal, typically as charcoal from or mimicking natural fire to adsorb PAHs and other

organic contaminants, has been relatively well assessed [118, 119].

Since metals are broadly conserved in pyrolysis, the total metal content of biochar will be determined largely by the feedstock content and the yield of char. The higher the carbon content of the char, the lower will be the mass concentrations of metals. On a biochar mass basis, the metal concentrations in products from gasification where char yield is small (a few to 10%) are likely to be up to tenfold higher than in slow pyrolysis. Data on the availability of metals from charcoal or biochar in soil is lacking. However, the potential for pyrolytic char to remediate land contaminated by metal cations has been demonstrated [120].

Stability of Biochar Carbon About 60% of the literature evaluated in [7] related to the stability of charcoal or to the quantification of char in soil (equally divided). Stability has been addressed both in real-time observation, where sensitivity can be enhanced through isotope tracers [121, 122], or extrapolation from measurements of soils from systems routinely experiencing natural fire [8, 106, 107]. In three cases, the effects of biological activity enhanced by substrate addition have been investigated [108, 111, 122]. Only in one case has pyrolysis char been evaluated [123] and, most often, the feedstock has been wood-derived.

Inference from measurements on soils in systems subject to natural fire suggests millennial stability, and in extrapolation from controlled incubations (elevated temperature and optimal moisture), the general acceleration of mineralization (decomposition) that occurs in such systems has been noted and accounted for [124].

Newly formed char appears to contain a small biologically labile fraction (see below), alkaline pH (mean pH = 8.5; ten studies), and nutrients available in ash from partial combustion embedded in the residual matrix. Only in one published study is this labile fraction deliberately extracted prior to evaluation [125]. Allowing for these characteristics that may lead to nonlinear carbon loss, other deficiencies in laboratory studies (simulation of natural char formation), and effects of induced changes in soil chemistry, the assumption of centennial to millennial stability does not appear unreasonable [122].

Experiments using newly formed charcoal have generally used particles <2 mm diameter (with no minimum particle size), but it has been noted that the physical fate of charcoal is predominantly in fine fractions, broadly <50 μm [90], and that its physical diminution appears relatively rapid, presumably through physical weathering and abrasion. There appears to be substantial evidence for intimate mineral–char interactions which, it has been hypothesized, might guard against degradation; however, discrete char particles have been found to persist within free organic fractions over a period of decades [126].

Three studies found no evidence for a role of tillage in the mineralization of wood-derived charcoal [122, 126, 127], and the single study that has explicitly examined the stability of pyrolytic char from wood and cereal straw suggested a slow and predominantly abiotic degradation which has been convincingly demonstrated for wood charcoal in a climosequence, which confirmed the sensitivity of absolute rates of degradation to temperature [33].

Oxidative measures are one of the key methods used to quantify char in soil, however they are used with the objective of retaining all charcoal in order to identify the wide continuum of char on soil (ranging from black carbon to soot), rather than identifying more or less stable subcomponents. However, the potential to develop artificial aging techniques (that simulate enzymatic oxidative degradation in soils) to rapidly compare and evaluate biochar stability (relative to charcoal) appears to have been rather overlooked and will be useful in seeking greater certainty on this critical matter [113, 112].

Labile Biochar Fractions Incubation of soil with manufactured or un-aged char typically results in higher CO_2 evolution than from the same soil without char. However, the degree of excess declines over time in a strongly nonlinear fashion in the short term [121, 123, 128–130]. This suggests a “priming” of decomposition of carbon, either of that already in the soil, or more likely of carbon in the added char. Priming of existing soil carbon could be a consequence of the modification of the soil-chemical environment (see below), while loss of carbon from biochar can result from the mineralization of a labile char fraction. These patterns also suggest that priming is complex and that extrapolation of stability using short-term decay rates

will be unreliable; such rates are not consistent with the age of charcoal found in archaeological soils such as the *terra preta*. The parameters that govern the balance between labile and stable components are not yet fully understood.

Priming of Soil Carbon or Biochar Loss The potential for biochar, in the form of synthetic charcoal, to cause or accelerate the decomposition of preexisting soil organic matter (priming) has been reported in medium-term study of litter layers in the boreal zone [131]. The loss of litter carbon was measured over a period of 10 years, but almost all the loss occurred prior to the first annual sampling. The litter into which charcoal was introduced was likely to be acidic and nutrient constrained, in which case the decomposition response is expected.

In Canada, and with the benefit of a carbon isotope trace, information on priming in tilled arable soil was obtained on a 65-year timeframe. This indicated that the mean residence time for particulate organic matter in soil increased by a factor of 2.5 at sites where charcoal derived from historic natural fire was present [126]. Another study, also with a carbon isotope trace, suggested slower and less complete utilization (high stabilization) of organic material added to soils from a tropical environment containing aged charcoal [132].

A single laboratory study [111] showed an approximate doubling of charcoal degradation rates (charcoal priming) with the addition of glucose to soil, a compound often used as a simple analogue for the labile carbon exuded into soil by living plant roots. The initial rates of loss were still low (0.5% over 60 days, which is a smaller proportion of charcoal carbon that might reside in a labile charcoal component) – especially for higher temperature char created from wood and for an experiment conducted under optimal conditions in a sand matrix. Quantitative extrapolation of such laboratory studies to the priming that might be likely to occur in the field, particularly with contrasting levels of microbial and plant root activity, is difficult.

It has been noted that if priming of soil organic matter is a permanent function of charcoal, the amount of non-charcoal carbon present under equilibrium field conditions must be lower than in charcoal-free soils [133]. Available data do not support this, and the Amazonian *terra preta* are enriched in organic matter

relative to the surrounding soils, as well as containing large amounts of aged charcoal. Due to climatic influences, the Amazonian soils are rather low in organic matter naturally. The likelihood of an analogous accumulation in temperate soils amended with biochar is not certain, given higher background soil-carbon mineralization rates. Other studies have also suggested stabilization of soil organic carbon pools [134] and suppression of CO₂ production in biochar-amended soils [135].

Biochar and Soil Nutrient Dynamics Reported increases in crop yield with charcoal addition have precipitated a number of plot-scale field trials to evaluate impacts on soil fertility, mainly through crop grain or biomass yield, usually with some measure of nutrient uptake. Reviewing 19 relevant articles in the literature [7], none of the reported studies have been

undertaken in temperate zones. As such, caution should be adopted in directly transferring knowledge gained from tropical environments to temperate regions. In the tropical environment, the impacts have generally been positive, though most often in combination with fertilizer nitrogen. Less than one third of these studies have used char application rates of less than 15 tC ha⁻¹, however, and only three used pyrolytic char.

Verheijen et al. [2] undertook a meta-analysis of the effects of biochar addition to soil on crop production using nine studies (all of which used replicates to measure variance), involving 86 separate “treatments”. The results are reproduced in Fig. 12.

The sample means indicate a small, but positive, effect on crop productivity with a grand mean of c. 10%. While there is some apparent trend of increased biochar additions, resulting in higher yields, this is not

Biochar, Tool for Climate Change Mitigation and Soil Management. Figure 12
The percentage change in crop productivity upon application of biochar at different rates from a range of feedstocks along with varying fertilizer co-amendments. *Points* represent mean, and *bars* represent 95% confidence intervals. Numbers next to bars denote biochar application rates (t ha⁻¹). Numbers in the two columns on the right show number of total “replicates” upon which the statistical analysis is based (***bold***) and the number of “experimental treatments” which have been grouped for each analysis (*italics*) (Reproduced with permission from Verheijen et al. [2])

statistically significant at the $P = 0.05$ level as can be seen from the overlapping error bars at the 95% confidence interval. Biochar additions at rates of 10, 25, 50, and 100 t ha^{-1} led to statistically significant increases in crop yields compared to a control with no addition, though other studies using 40 and 65 t ha^{-1} did not show any statistically significant yield increase. Figure 12 illustrates that there is a wide variance in the response to biochar addition, e.g., at the 5.5, 11, and 135.2 t ha^{-1} application rates. Verheijen et al. speculate that the reasons for this are variability in the biochar, crop, and soil types. They also note that the means for each application rate are positive, and that no single biochar application rate had a statistically significant negative effect on crop productivity (though individual experiments have demonstrated negative effects, e.g., [84], [159]). On the other hand, the studies they examined do not cover a wide-range of latitudes and are heavily skewed toward (sub-) tropical conditions.

Substituting chemical fertilizer for the nutrients added into the soil as biochar has not resulted in the same increase of crop productivity as provided by biochar addition. In two cases where the effect of pH modification was controlled for by liming, the effect of char was still superior [7]. This suggests that char might impact crop growth through its impacts on soil physical properties and/or on mediation of nutrient exchange between soil and plant.

In classic studies of *terra preta* fourth-season maize yields were much higher in plots amended with char and fertilizer than the non-fertilized and non-char amended control [136], and similar results have been shown in experiments with maize carried out in Columbian savannah soil [137]. However, regarding the *terra preta* studies, it is strictly incorrect to say that the effect of the treatments was to increase yield, since the yields for all treatments displayed post-clearance decline, and the control yields were ultimately very low.

Limited evidence under tropical soil conditions suggest that the addition of fresh charcoal can reduce nitrogen leaching loss. Soils with higher and long-established charcoal content had enhanced nutrient status but leached extra added nitrogen [1]. There is a relatively large amount of consistent evidence for the partial surface oxidation of char by chemical and

biological processes in soil and proliferation of carboxyl groups [138]. It appears that this is reflected in the cation exchange capacity of aged charcoal and charcoal-rich soils, but not shown in new char. Plot-scale experiments indicate that the uptake of other nutrients may be enhanced by charcoal, in particular phosphorus as ash in charcoal may be more available than phosphate in the soil.

Since biochar has a high carbon-to-nitrogen ratio, it is likely that rapid mineralization of a labile carbon fraction could – by immobilization – contribute to a draw on soil mineral nitrogen, in addition to an effect of ammonium sorption, and potentially reduce crop nitrogen supply. Evidence for this effect is relatively abundant and consistent in the literature, but the effect depends on the status of indigenous soil mineral nitrogen, and these studies have been undertaken exclusively in the tropics.

Immobilization tends to enhance soil nitrogen supply to the crop in the longer term since microbial proliferation builds a reservoir of mineralizable nitrogen. In field studies of charcoal or biochar extending beyond a single season, this effect may be observed, where second- or subsequent-season (but not first-season) are elevated relative to non-amended controls.

Biochar and Emission of Nitrous Oxide and Methane from Soil

A single peer-reviewed study reports suppression of nitrous oxide emission from soil from charcoal [125]; however, in the light of the importance of N_2O emissions to total agricultural greenhouse gas emissions and emerging evidence reported in recent studies (e.g., [13, 139, 140, 141]) the effect warrants further attention. Results from planted fields in Columbia showing a large positive effect are unpublished [142] as are three studies showing conflicting outcomes in laboratory studies using soils from Australia [143, 144] and New Zealand [139]. Laboratory studies used high rates of application [125, 135], single soils [145], or single types of charcoal. Results from a laboratory study using biochar made from poultry manure and *Eucalyptus* wood showed N_2O emissions were reduced over a long-term (5-months with three wet-dry cycles) period [140].

Nitrous oxide is emitted mainly by specific groups of bacteria, which under anaerobic conditions reduce nitrate rather than oxygen (nitrate to N_2O via nitrite

and nitric oxide). Emission of N_2O at low rates may also occur under aerobic conditions from the activity of chemotrophic bacteria converting mineralized organic nitrogen (ammonium) to nitrate. Higher soil organic matter increases nitrification, but the application of nitrogen fertilizer has a greater immediate impact on soil nitrate concentrations and, hence, N_2O emission.

Proposed mechanisms for biochar suppression of N_2O revolve around modification of soil-water dynamics, e.g., drawing soil solution and dissolved nitrate into inaccessible pores (small pores saturating first) and maintaining aerobicity in inhabited soil-pore space; increase of soil pH which under anaerobic conditions favors completion of nitrate reduction to N_2 from N_2O ; or the adsorption of ammonium and its protection from nitrification and denitrification [125, 145, 146]. Singh et al. [140] also propose the importance of time-induced changes (“aging”) on biochar properties which were attributed to the reduction in ammonium leaching and N_2O emissions they observed.

The effect of water addition cannot be completely evaluated under constant conditions, but Yanai et al. [125] found suppression was reversed when water-filled pore space was increased from partial to near-complete saturation. In the same study, the addition of combustion ash to the soil, separately from charcoal, did not suppress emission. However, [140] and [147] have demonstrated reduced N_2O emissions after a sequence of wet-dry cycles. Therefore, there is the important influence of time which must be taken into consideration. Simultaneous monitoring of N_2 is also required to confirm N_2O reduction. It has also been shown that nitrate has also been reported to accumulate where N_2O is suppressed [147].

Mobility of Char Biochar and charcoal fines have a low bulk density of approximately 300 kg m^{-3} against a typical soil bulk density of $1,300 \text{ kg m}^{-3}$. Particles may be very fine in size and, in addition, surfaces may be hydrophobic [148]. Collectively, these characteristics indicate a higher potential for lateral transfer in water than for other soil components [149], and applied at a high rate in tropical environments subjected to frequent intense rainfall, erosion of charcoal off-site has been measured in proportions up to 25% in 2 years [150], and most of the 66% loss

calculated by Nguyen et al. [106] in 30 years after surface deposition was attributed to erosion.

Negligible longer-term losses [106] and low rates of movement apparent for natural charcoal in a temperate environment [126] suggests a rapid decline in hydrophobicity, physical breakdown, and development of association with mineral particles [87, 151, 152]. The “anchoring” of particles within the soil matrix at depth may be critical in limiting erosion. The apparent combustion of fire-derived char in dry regions, where material remains at the surface between fires [153, 154], emphasizes the role of incorporation into deeper soil in ensuring longevity in the natural environment, and that in more biologically active soils, this must therefore occur. However, measured rates of transport into subsoil appear to be slow [150].

Meanwhile, studies of the global cycle of “black carbon” have established the existence of significant flux from land to ocean at a macroscale [102, 155]. Little literature has addressed the process of transport of char through the environment, although it has been noted that PAH is high in organic matter dissolved in alkali extracts after natural fire [156].

Char, Soil-Water Dynamics, and Irrigation In large quantities, wood-derived charcoal modifies soil physical properties. It has a low-inherent bulk density of $0.3\text{--}0.5 \text{ t m}^{-3}$, which is one third to one fifth that of typical NW European arable soil. Depending on particle-size distribution of the char relative to that of the soil and the extent to which added char may locate within existing pores, higher experimental rates of application could directly reduce soil bulk density and increase soil volume. This affects water-holding capacity and water-filled pore space, but declining hydrophobicity and the effects of weathering on particle size will determine the duration of this effect. In the experimental context, water-holding capacity is measurably increased by adding fresh charcoal and must be considered in the design of laboratory soil incubations [132]. Studies of amended soils can be adjusted for either equal gravimetric water content, or to equal tension (depending on the hypothesis). Water storage could be of critical value, yet the factors that determine the efficacy of char in this context have not been clarified.

Published evidence [88] for the effect of biochar on pore-size distribution, however, is remarkably scarce.

Some assessments have been made, and the problem appears to be in the level of replication required to demonstrate significant affects using methods best used in comparison of different soils. One study [157] has reported water-holding capacity of soils amended at low, medium, and high rates with pyrolytic char; one study has focused solely on pore-size characteristics of charcoal and pyrolytic char [88]; and one has measured the impact of charcoal residues on water-holding capacity at old kiln sites [83].

Summary

The evidence for the function of biochar in soil is based largely on evidence from studies of charcoal, and predominantly in the tropical environment. Triangulation of existing knowledge with systematic studies of biochar produced using technology and feedstocks relevant to viable temperate systems is needed, combined with techniques to rapidly assess long-term stability, and potential soil agronomic benefits.

Conclusion: Evaluating the Sustainability of Pyrolysis-Biochar Systems

A *sustainable biochar system* can be defined as one which: (a) produces and deploys biochar safely and without emitting non-CO₂ greenhouse gases; (b) reduces net radiative forcing; (c) does not increase inequality in access to and use of resources unduly, and (d) provides an adequate return on investment. Condition (a) is important to ensure that PBS technologies and practices do not pose undue risks to human health and safety and the environment (e.g., through inhalation of dust, biochar particles turning waterways or surrounding vegetation “black,” adding N₂O, CH₄, or black carbon soot particles to atmosphere increasing net greenhouse forcing, etc.). Condition (b) is important to ensure that the net result of a PBS is indeed to reduce net radiative forcing relative to a baseline case. This is primarily due to reduction in atmospheric concentration of greenhouse gases through removal and avoided emissions. Condition (b) also takes account of direct and indirect land-use changes (I/LUC), which can result in one-off emission of hundreds of tons of carbon per hectare in the case of tropical and peatland rainforest. Clearing of Brazilian wooded *cerrado* incurs a carbon loss of c. 45 tC ha⁻¹, US

grassland c. 30 tC ha⁻¹, and abandoned US crop land zero or only a few tons per hectare [160]. Clearly, there is no point in converting land that incurs a large loss of carbon to biomass production for energy if the main purpose (or a large part of the rationale) of a project is to abate carbon through biochar production.

Condition (c) is relevant because an increase in demand for biomass will have knock-on impacts upon other users or potential users of that biomass, or upon other biomass, demand for which increases due to substitution effects. This also relates to LUC and ILUC, which frequently encounters equity and justice problems and questions. Condition (d) refers to economic viability since in market economies investment will only follow favorable rates of return. Defining an “adequate rate of return” is fraught with difficulties and depends upon subjective considerations such as the discount rate selected.

Systems which meet all of the above criteria do not exist at demonstration or commercial scale at the current time, and do not include traditional charcoal production. This is not surprising, of course, because biochar has only been proposed as a carbon abatement and agronomic improvement technology since the early- to mid-2000s. The further development and eventual deployment of biochar will be driven by one or more of the following policy and economic drivers.

- (a) *Agronomic value of the biochar*: This value could be quite large on depleted soils, but any value has to be offset against the costs of production, delivery, and application to soil. Where the biochar is a by-product of electricity (or heat) generation, it may have a zero production cost. Examples of zero-cost biochar are few and far between and unlikely to be the norm. The cost of biochar production will, in many cases, be hard to recoup from the value of the agronomic gain alone.
- (b) *Carbon storage value of the biochar*: If biochar can be ascribed a carbon storage value, this could greatly accelerate its successful take-off. The difficulty in ascribing a carbon value to biochar relates to the scientific uncertainty over long-term stability and interactions with soil organic carbon, lack of agreement on (and difficulty relating to) inclusion of land-based carbon budgets in trading arrangements, and technical uncertainties around

Monitoring, Verification, Accounting, and Reporting (MVAR).

- (c) *Waste management*: If pyrolysis-biochar systems are a cost-effective way of dealing with certain organic waste fractions (relative to other disposal/management options), this could drive the deployment of PBS through the value of the avoided tipping-fees to waste-management companies. The difficulty of this route is that waste biochar products are likely to pose more environmental and health and safety risks and will need to be carefully assessed and controlled. Such regulation is likely to drive-up the costs of biochar from wastes and to increase the regulatory barriers and hurdles, reducing interest from the industry. Furthermore, tipping fees are related to land-fill costs and taxation, which are subject to political change.
- (d) *Renewable energy incentives*: To make pyrolysis-biochar add-up, it is likely that incentives will be required for the generation of renewable electricity and/or heat. Where the incentives are for electricity generation, however, other thermal conversion technologies such as combustion and gasification (with limited char production) will frequently have a competitive edge. Such incentives and subsidies are also vulnerable to political change.
- (e) *Agri-environmental policies*: Another potential route to biochar deployment is through appropriate agri-environmental policies. If biochar addition can be demonstrated to have multiple benefits to agricultural land, agricultural support policies could be used to promote its adoption, for example, through inclusion in measures that are eligible for area-based and environmental stewardship payments.

One way forward in the short- to medium-term is to promote the use of biochar in particular niche applications, where its potential can be demonstrated and from there broader applications identified. This is broadly consistent with the innovation studies literature on socio-technical transitions: new technologies nearly always begin as niche applications that, if useful, find a wider role (3). The identity of the niche application will vary, depending on local, national, and regional context; policy; and socioeconomic drivers and incentives. In Europe, it may be sustainable biochar

production from particular organic waste streams (paper or sewage sludge, for example), while in Asia, it may be carbonized rice husks from a gasifier as described in Box 2. In North America and Scandinavia, woody wastes from the timber industry may be ideal feedstocks, while in Africa, agricultural residues that would otherwise be burnt may offer-up opportunities.

Future Directions for Research, Development, and Demonstration

Biochar is a complex, multifunctional material that requires improved mechanistic knowledge and understanding – of its production, properties, impacts, interactions, costs, and benefits. Without this mechanistic process understanding, it is difficult if not impossible to predict and assess accurately the benefits of biochar for either greenhouse gas abatement or for addition to the soil even with evidence from individual field trials. We have identified the key research needs according to three broad headings below.

Pilot Production Research Facilities for Biochar and “Engineered” Biochar

What is the need? A strategic approach to producing, testing, and comparing biochar samples from different technologies, under specific reproducible conditions, would improve the evidence base. Facilities are needed to serve the research community, focusing current and future effort away from charcoal and toward biochar, produced from designated feedstocks under highly specified process conditions.

Why? The engineering and technological challenges are intimately related to the engineered biochar concept – namely engineering biochar with specific and controlled properties, designed for particular purposes (e.g., carbon abatement, short- and long-term agroeconomic gain, waste-management and pollution control, energy production, etc.) and contexts of application (soil types, agricultural systems, other land-uses, etc.).

When? The need is urgent if biochar is to have a role in tackling climate change in the next several decades and necessary for any future soil application of biochar.

Resource implications: The resources required are reasonably large, but not large compared to much technology-development since biochar can be

produced at small-scales using relatively straightforward equipment.

How well advanced is existing research? There is currently limited activity or capacity anywhere in the world for technological evaluation of biochar production.

Ability to address key questions: Once equipment is in place, it should be relatively straightforward to address the key questions which arise, though some issues will inevitably take time to answer.

Examples of key questions to address:

Recipes for producing engineered biochar with specific properties and functions – acquiring the technological know-how to produce biochar with defined properties based upon a process understanding of production conditions.

Better understanding of the carbon and energy balance of alternative biochar production technologies – as yet there is little consistent and high-quality data on pilot- and commercial-scale pyrolysis (especially slow and intermediate) without which any evaluation of biochar is impaired.

Better understanding of the superlabile, labile, and stabilized components of biochar – better knowledge of what influences the Carbon Stability Factor for biochar is required, along with the effects in soil and field of labile versus stable carbon.

The Predictability and Certainty of the Impacts of Biochar

What is the need? If biochar is to be a commercial proposition, it will be necessary for reliable predictive knowledge of its impacts in particular soil and agro-economic contexts to be well established (just as is the case for chemical fertilizers or pesticides). There is also need for a practical and scalable method by which the stable component of biochar can be established experimentally through acceleration of initial degradation as well as for examining the change that occurs soon after incorporation in soil.

Why? Only if the user is confident of positive and cost-effective benefits of biochar, when applied at particular rates, will a biochar market emerge. If the purpose is solely carbon storage, then the key issue will be long-term stability of the biochar.

When? For the purposes of carbon storage, urgent knowledge of long-term stability will be necessary. Predictive knowledge of soil and plant impacts is necessary for development of a market for biochar addition to land.

Resource implications: the resources required are moderate, but progress is being held back by lack of samples and equipment.

How well advanced is existing research? Evidence for the stability of charcoal in agriculture and the wider environment has been inferred in detailed studies in the USA and Australia. Work on the definition and stability of biochar is ongoing by established research groups. Work on soil and plant effects is well established internationally (especially in the USA, Australia, Brazil and Japan). However, this research is still in its infancy with no systematic effort: the opportunity exists for a focused and deterministic approach.

Ability to address key questions: In principle, it should be possible to address the stability question relatively quickly. Addressing the soil and plant effects will be more complex and time-consuming because of variability and complexity.

Examples of key questions to address:

These questions/topics can be addressed/answered fairly quickly.

Short- and long-term effects – separating out the long-term and short-term effects of biochar by comparing the functions of fresh and artificially aged material

Available nutrients and contaminants – Agreement on a methodology to quantify “available” nutrients and contaminants in a biochar matrix.

Deployment equipment and appliances – Develop modifications of existing agricultural equipments and implements so as to develop effective and efficient ways of storing and deploying biochar in realistic farm-based scenarios.

Biochar in grassland systems – The potential to reduce methane emissions from cattle, biochar as a slurry additive for odor control, etc.

Methodologies for evaluating the migration of biochar by movement through the soil profile, wind-erosion, water-erosion, etc. – necessary for regulation and carbon accounting.

Low-cost monitoring of biochar – Investigation of field spectroscopy and remote sensing for the low-cost monitoring of biochar added to soil.

These questions/topics are more difficult, complex, and/or simply time-consuming, and will take longer to address or answer

Nitrous oxide suppression – Examination of the mechanism by which biochar, at least under certain conditions, can suppress nitrous oxide emission from soil.

Field experimentation and trials strategy – Field experiments and trials that encompass diverse rotations and systems (arable, horticulture, and grassland) and including feedstocks derived from (inter alia) agricultural residues.

The value of biochar-based soil management – Compare the likely value of biochar-based soil management against the return that has been established for active use of other organic resources in management of soil.

Biochar for the control of diffuse pollution – More research on the ability of biochar to reduce leaching from land (e.g., using buffer ditch experiments) or from other sources (e.g., waterways, road surfaces).

Wider Biochar Sustainability Issues

What is the need? What are the wider impacts of biochar as a system, potentially deployed at different scales and in different spatiotemporal and socioeconomic contexts? How can the biochar system be made sustainable?

Why? Pyrolysis biochar systems (PBS), or variants thereof, only make sense if they meet minimum sustainability requirements (standards) and avoid incurring adverse environmental, social, or economic impacts. Sustainability appraisal methods can be utilized to ensure that biochar at a system level “adds-up”

When? It is important to understand system level impacts as these help direct more basic research and development by identifying key sensitivities. It is necessary to evaluate system-level effects prior to real-deployment to understand knock-on effects and potential problems.

Resource implications: The resources required are small compared to the technological and basic

scientific research and development required because equipment and experimental costs are typically lower.

Ability to address key questions: Rapid progress can be made once resource is available, though accuracy and precision is dependent upon the availability of new data from technological and natural scientific R&D.

Examples of key questions to address:

Better Life-Cycle Assessments of pyrolysis-biochar systems – improved data across the whole PBS supply chain (from feedstock to field) and alternative biochar-producing systems.

Better techno-economic cost modeling – using more accurate data and with an improved representation of the key processes and stages, including production, distribution, storage, and deployment.

Better comparative analyses of biochar versus other resource-use options – need for explicit and transparent comparisons using best-available data of the most effective way of using and managing limited biomass resources for, e.g., bioenergy generation, carbon/greenhouse gas abatement, sustainable soils and waste management, composting and sustainable agri-food systems.

Assessment of land-use implications of biochar deployment – how biochar might influence the competitive advantage of different crops and the knock-on impacts on land-use decisions, supply, and demand.

Acknowledgments

We would like to acknowledge financial support from the UK's Engineering and Physical Sciences Research Council (EPSRC), the UK Government, and the European Regional Development Fund (Interreg IVb) in supporting the UK Biochar Research Centre.

Absolute humidity Absolute humidity is defined as the weight of water vapor contained in a unit volume of air. Typical units are pounds of water per pound of dry air or grains of water per cubic foot. Absolute humidity is also known as the water vapor density (D_v).

Celsius temperature ($^{\circ}\text{C}$) Celsius temperature ($^{\circ}\text{C}$) refers to temperatures measured on a scale devised in 1742 by Anders Celsius, a Swedish astronomer. The Celsius scale is graduated into 100 units between the freezing temperature of water (0°C) and its boiling point at normal atmospheric pressure (100°C) and is, consequently, commonly referred to as the *centigrade scale*.

Dew-point temperature (DPT) Dew-point temperature (DPT) is the temperature of a surface upon which water vapor contained in the air will condense into liquid water. Stated differently, it is the temperature at which a given quantity of air will become saturated (reach 100% relative humidity) if chilled at constant pressure. It is thus another indicator of the moisture content of the air. Dew-point temperature is not easily measured directly; it is conveniently found on a psychrometric chart if dry-bulb and wet-bulb temperatures are known.

Dry-bulb temperature (DBT) Dry-bulb temperature (DBT) is the temperature measured in air by an ordinary (dry bulb) thermometer and is independent of the moisture content of the air. It is also called “sensible temperature.”

Fahrenheit temperature (F) Fahrenheit temperature (F) refers to temperature measured on a scale devised by G. D. Fahrenheit, the inventor of the alcohol and mercury thermometers, in the early eighteenth century. On the Fahrenheit scale, the freezing point of water is 32°F and its boiling point is 212°F at normal atmospheric pressure.

Humidity Humidity is a general term referring to the water vapor contained in the air. Like the word “temperature,” however, the type of “humidity” must be defined.

Relative humidity (RH) Relative humidity (RH) is defined as the percent of moisture contained in the air under specified conditions compared to the amount of moisture contained in the air at total saturation at the same (dry-bulb) temperature. Relative humidity can be computed as the ratio of existing vapor pressure to vapor pressure at saturation, or the ratio of absolute humidity to absolute humidity at saturation existing at the same temperature and barometric pressure.

Water vapor pressure (P_v) Water vapor pressure (P_v) is that part of the atmospheric pressure exerted due to the amount of water vapor present in the air. It is expressed in terms of absolute pressure as inches of mercury (in. Hg) or pounds per square inch (psi).

Wet-bulb temperature (WBT) Wet-bulb temperature (WBT) is an indicator of the total heat content (or enthalpy) of the air, that is, of its combined sensible and latent heats. It is the temperature measured by a thermometer having a wetted sleeve over the bulb from which water can evaporate freely.

Definitions

Bioclimatic design – combining “biology” and “climate” – is an approach to the design of buildings and landscape that is based on local climate. The approach was promoted in a series of professional and popular publications in the 1950s [1, 2]. In using the term “bioclimatic,” architectural design is linked to the physiological and psychological need for health and comfort. In adopting bioclimatic approaches, the designer endeavors to create comfort conditions in buildings by understanding the microclimate and resulting design strategies that include natural ventilation, daylighting, and passive heating and cooling. The premise of bioclimatic design is that buildings utilize natural heating, cooling, and daylighting in accordance with local climatic conditions.

Resilient design is an extension of bioclimatic design. It adds precautionary measures to provide health and safety to prepare for natural disasters, including extreme storms and flooding of inland watersheds and coastal areas. The concept of resiliency applies lessons from natural systems to design for extreme conditions using strategies found in natural systems, such as buffering, zone separation, redundancy, rapid feedback, and decentralization.

Introduction

Bioclimatic design had been part of practical knowledge of indigenous building throughout historical periods, including early modern architecture. When air-conditioning systems became widely available at the end of the 1950s, interest in bioclimatic design became less evident in professional and popular literature and in built work. The topic reemerged in response to energy shortages of the 1970s – when “passive solar design” became the popular term to describe the approach, at first emphasizing solar heating but soon broadened to passive cooling and daylighting.

With the emergence of global environmental concerns of the 1990s – recognizing that energy conservation has “cascading” effects and benefits in reducing pollution and in mitigating global warming – the scope of bioclimatic design was enlarged to include landscape, water, and waste nutrient recovery. *Sustainable design* of architecture and communities emerged as an approach to protect and improve the biological health of communities conceived as the ecology of building, site, and region.

Some bioclimatic design techniques – earth sheltering is an example – can contribute to comfort and reduce both heating and cooling loads year round. Other techniques are useful only part of the year. The effectiveness of passive solar heating, for example, is very specific to the need for heating and otherwise needs to be tempered by sun shading and thermal mass. Natural ventilation can provide comfort in all seasons, especially in summer when it can reduce or eliminate the need for air-conditioning in some climates.

All buildings experience interruptions of conventional energy availability, often coincident with weather extremes and natural disasters. A precautionary approach to the design of all buildings is to provide bioclimatic means to insure subsistence levels of heating, cooling, and daylighting for comfort, health, and safety in case all power sources are interrupted. For the longer term, in which conventional energy shortages and emergencies are unpredictable, buildings without natural heating, cooling, and lighting impose serious liabilities on occupants and owners.

Strategies of Bioclimatic Design

Bioclimatic design strategies are effective for “envelope-dominated” structures – such as homes

and one- or two-story facilities – to provide a large portion if not all of the energy required to maintain comfort conditions.

“Internal load dominated” buildings – such as hospitals, offices, commercial kitchens, and windowless stores – experience high internal gains imposed by the heat of occupancy, lights, and equipment. In such cases, the external climatic conditions may have less influence on achieving comfort and low energy utilization. However, as internal loads are reduced through energy-efficient design – such as low-wattage lighting, energy-efficient equipment, occupancy scheduling and zoning – the effects of climate become more obvious and immediate. All buildings can benefit from available daylighting, but large glazed areas require careful shading control, glazing selection, and possibly night insulation.

The “resources” of bioclimatic design are the natural flows of energy in and around a building – created by the interaction of sun, wind, precipitation, vegetation, temperature, and humidity in the air and in the ground. In some instances, this “ambient energy” is useful immediately or can be stored for later use. There are definable “pathways” by which heat is gained or lost between the interior and the external climate in terms of the classic definitions of heating energy transfer mechanics. From these, the resulting bioclimatic design strategies can be defined (Fig. 1 and Table 1).

- **Conduction** – from hotter objects to cooler objects by direct contact.
- **Convection** – by flow of air between warmer objects and cooler objects.
- **Radiation** – from hotter objects to cooler objects within the direct view of each other regardless of the temperature of air in between, including radiation from sun to earth.
- **Evaporation** – the change of phase from liquid to gaseous state: The sensible heat (dry-bulb temperature) in the air is lowered by the latent heat absorbed from air when moisture is evaporated.
- **Thermal storage** – from heat charge and discharge both diurnally and seasonally, as a function of its specific heat, mass, and conductivity. Although not usually listed alongside the four classic means of heat transport, this role of thermal storage is helpful in understanding the heat transfer physics of building climatology.

Bioclimatic Design. Figure 1

Paths of energy exchange at the building microclimate scale.

Bioclimatic design is based upon understanding energy flows within and around buildings (Watson and Labs [13])

In winter (or underheated periods), the objectives of bioclimatic design are to resist loss of heat from the building envelope and to promote gain of solar heat. In summer (or overheated periods), these objectives are the reverse, to resist solar gain and to promote loss of heat from the building interior. The strategies can be set forth as:

- **Minimize conductive heat flow.** This strategy is achieved by using insulation. It is effective when the outdoor temperature is significantly different, either lower or higher, than the interior comfort range. In summer, this strategy should be considered whenever ambient temperatures are within or above the comfort range and where natural cooling strategies cannot be relied upon to achieve comfort (i.e., whenever mechanical air-conditioning is necessary).
- **Delay periodic heat flow.** While the insulation value of building materials is well understood, it is not as widely appreciated that building envelope materials also can delay heat flows that can be used to

^aProperly described as “underheated” and “overheated”

^bIn overheated periods where air-conditioning is required

^cThermal storage may utilize “phase change” materials and the latent heat capacities of chemicals such as eutectic salts

improve comfort and to lower energy costs. Time lag through masonry walls, for example, can delay the day’s thermal impact until evening and is a particularly valuable technique in hot arid climates with wide day-night temperature variations. Techniques of earth sheltering and berming also exploit the long-lag effect of subsurface construction.

- *Minimize infiltration.* “Infiltration” refers to uncontrolled air leakage around doors and windows and through joints, cracks, and faulty seals in the building envelope. Infiltration (and the resulting “exfiltration” of heated or cooled air) is considered the largest and potentially the most intractable source of energy loss in a building, once other practical insulation measures have been taken.
- *Provide thermal storage.* Thermal mass inside of the insulated envelope is critical to dampening the swings in air temperature and in storing heat in winter and as a heat sink in summer.
- *Promote solar gain.* The sun can provide a substantial portion of winter heating energy through elements such as equatorial-facing windows and greenhouses that include other passive

solar techniques which utilize spaces to collect, store, and transfer solar heat.

- *Minimize solar gain.* The best means for ensuring comfort from the heat of summer is to minimize the effects of the direct sun by shading windows from the sun, or otherwise to minimize the building surfaces exposed to the summer sun by use of radiant barrier and by insulation.
- *Minimize external air flow.* Winter winds increase the rate of heat loss from a building by “washing away” heat and thus accelerating the cooling of the exterior envelope surfaces by conduction, and also by increasing infiltration (or more properly, exfiltration) losses. Siting and shaping a building to minimize wind exposure or providing wind-breaks can reduce the impact of such winds.
- *Promote ventilation.* Cooling by air flow through an interior may be propelled by two natural processes, cross-ventilation (wind driven) and stack-effect ventilation (driven by the buoyancy of heated air even in the absence of external wind pressure). A fan (using photovoltaic for fan power) can be an efficient way to augment natural ventilation cooling in the absence of sufficient wind or stack-pressure differential.

- *Promote radiant cooling.* A building can lose heat effectively if the mean radiant temperature of the materials at its outer surface is greater than that of its surroundings, principally the night sky. The mean radiant temperature of the building surface is determined by the intensity of solar irradiation, the material surface (film coefficient), and by the emissivity of its exterior surface (its ability to “emit” or reradiate heat). This contributes only marginally, if the building envelope is well insulated.
- *Promote evaporative cooling.* Sensible cooling of a building interior can be achieved by evaporating moisture into the incoming air stream (or, if an existing roof has little insulation, by evaporative cooling the exterior envelope such as by a roof spray). These are simple and traditional techniques and most useful in hot-dry climates if water is available for controlled usage. Mechanically assisted evaporative cooling is achieved with an economizer-cycle evaporative cooling system, instead of, or in conjunction with, refrigerant air-conditioning.

Bioclimatic Analysis

Analysis of climatic data is a first step in bioclimatic design. Preliminary design direction and rules of thumb can be determined by graphing bioclimatic data. While the method can be done by hand, computer-assisted methods allow this approach to be increasingly accurate.

Humans are comfortable within a relatively small range of temperature and humidity conditions, roughly between 68°F and 80°F (20–26.7°C) and 20–80% relative humidity (RH), referred to on psychrometric charts as the “comfort zone.” These provide a partial description of conditions required for comfort. Other variables include environmental indices – radiant temperature and rate of airflow – as well as clothing and activity (metabolic rate). While such criteria describe relatively universal requirements in which all humans are “comfortable,” there are significant differences in and varying tolerance for discomfort and conditions in which stress is felt, depending on age, sex, health, cultural conditioning, and expectations.

Givoni [3] and Milne and Givoni [4] proposed a design method using the building bioclimatic chart, modified by Arens [5] (Fig. 2). The chart adopts the

psychrometric format, overlaying it with parameters for the appropriate bioclimatic design techniques to create human comfort in a building interior. If local outdoor temperatures and humidity fall within specified zones, the designer is alerted to opportunities to use specific bioclimatic design strategies to create effective interior comfort.

Computer-based simulation and energy design tools make it possible to utilize site-specific hourly weather data to analyze data for bioclimatic design. This makes it possible to compare bioclimatic design strategies for a given climate, comparing a proposed design with a “base case,” that is, the same building without a proposed design feature, such as south-facing glass, added insulation, shading, ventilation, and thermal mass.

Figure 3 depicts a simulated “representative winter week” (7 days) comparison of a “base case” house with a combined set of options, including solar-oriented windows (while decreasing windows on other orientations), increased insulation including nighttime curtains, and interior thermal mass. The “base case” house represented the US code-compliant national average construction, published by the National Association of Home Builders. Bioclimatic design strategies were added as achievable within a 5% increase in construction cost. The “representative winter week” represented a 30-year average winter week (November to January) in which 3 days of clouds were followed by 3 days of sunshine. Heat gains in Btu are indicated above the horizontal bars, and losses below it. The illustration indicates the benefit of the “solar pulse,” that is, passive solar gain in the 3 sunny days at the end of the 7 days (lower right), compared to negligible solar benefit in the Base case during the same sunny period (upper right). In this particular week, the combined passive strategies accomplished a 38% in energy requirement.

The example in Fig. 3 was part of a research project that compared a variety of bioclimatic features, singly and together, in 20 US cities [6]. The results supported several conclusions. Firstly, the relative effectiveness of any particular bioclimatic design technique is more than additive, that is, when combined they supported larger efficiencies in performance than when used singly. Secondly, when compared in different climatic zones, the rank order of most effective strategies changed – perhaps obvious, but worthy as

Bioclimatic Design. Figure 2

Building bioclimatic chart. The chart indicates parameters of local climatic conditions favorable for bioclimatic design strategies (Based on Givoni [3] and Arens [5])

confirmation that each climatic region has its own most appropriate design techniques. But finally, the difference between one top strategy and another was for the most part not so far ahead of others that there is any one answer. Designers have a choice, within a set of high performing strategies and techniques.

These findings are supported by a selective tabulation (Table 2), with results of the 20 city comparisons (simulated for a full year, compiling TMY data as available in 1984). For the four cities shown in Table 2, representatives of different US climates, the heating energy requirement is shown in blue and cooling in red. The “boxed” option indicates the most effective technique for combined heating and cooling energy for each location. In the case of Boston, the passive solar

and super-insulation options are approximately equal and either one represents a 40% reduction of energy required compared to the base house. The same strategies achieved more than 46% reduction in Seattle, 62% in Los Angeles, whereas none of the solar options outperformed an 18% improvement achieved simply outside insulated block walls in New Orleans. While such results are “imagined,” that is, the result of assumptions made in computation, they indicate the value of simulation to help understand the thermodynamics of climate, building design options, and resulting comfort and energy requirements.

Climatic data for computer simulation for locations worldwide are available on the Web. In regions of the world where extensive climatic data are not available

Base case house – Boston, MA

Bioclimatic Design. Figure 3

Simulation of bioclimatic design features. The simulation illustrates the energy performance of passive solar strategies compared to a base case in Boston, MA, climate (cool/temperate, partly sunny). (1) Heating energy required, (2) passive solar contribution, (3) thermal mass contribution, (4) roof heat loss, (5) heat loss various other surfaces (Watson and Harrington 1979. Unpublished manuscript)

and where, for example, data are limited only to monthly averages of temperature and humidity, the available data may not be coincident and must be interpreted with caution.

TMY summaries contain simultaneous climatic data for all 8,760 h in a “typical” year. Available for airport locations, mostly in the United States, each file contains one complete year of hourly data, including direct (beam) solar radiation, total horizontal solar radiation, dry-bulb temperature, dew-point humidity, wind speed, and cloud cover. Electronic files of climatic data for most US locations (major airports) are available through various sources on the Web from NREL [7]. Over 500 stations worldwide are available on the energy plus Web site [8].

Several papers by Arens [9, 10] describe techniques to interpolate multiple TMY3 data sets for locations “in between” airport locations to adjust them to match substation monthly means, or modify them further to account for the building-site surroundings.

Climate consultant is a computer-based program that can be downloaded at no cost from the Web [11]. Part of a career-long project of UCLA Professor Emeritus Murray Milne to develop public domain energy design tools [12], the software plots weather data, including temperatures, wind velocity, sky cover, percent sunshine, and beam and horizontal irradiation. It uses these data to create psychometric charts and plots hourly data in the above-mentioned zones that indicate timetables of bioclimatic needs, sun charts showing times of solar needs and shading requirements. It includes 3-D plots of temperature, wind speed, and related climatic data cross-referenced to bioclimatic design practices presented in Watson and Labs [13].

Figure 4 represents a typical bioclimatic chart generated by Climate Consultant. It displays an annual summary for Minneapolis and in the upper left, the percent (hours per year) that bioclimatic categories are effective.

Bioclimatic Design Practices

Each locale has its own bioclimatic profile, sometimes evident in indigenous and long-established building practices. Bioclimatic design techniques can be set forth as a set of design opportunities (adapted from Ref. [9]):

- *Wind breaks* (winter) – Two design techniques serve the function of minimizing winter wind exposure:
 - Use neighboring landforms, structures, or vegetation for winter wind protection.
 - Shape and orient the building shell to minimize winter wind turbulence (Fig. 5).
- *Thermal envelope* (winter) – Isolating the interior space from the hot summer and cold winter climate, such as:
 - Use attic space as buffer zone between interior and outside climate.
 - Use basement or crawl space as buffer zone between interior and grounds.
 - Use vestibule or exterior “wind-shield” at entryways.

Bioclimatic Design. Table 2 *Comparison of bioclimatic options in four US climates.* Requirements for heating (in blue) and cooling (in red) are compared for an identical “base case” house (code compliant). Different strategies are compared in representative US climates (Watson and Harrington [6])

	Base case ^a	Earth berms ^b	Trombe wall ^c	Block wall ^d	Passive solar ^e	Super insul. ^f

^gHeating energy required in Btu

^hCooling energy required in Btu

- Locate low-use spaces, storage, utility, and garage areas to provide climatic buffers.
- Subdivide interior to create separate heating and cooling zones.
- Select insulating materials for resistance to heat flow through building envelope.
- Apply vapor barriers to the warm side of building envelope assemblies to control moisture migration.
- Develop construction details to minimize air infiltration and exfiltration.
- Provide insulating controls at glazing.
- Use heat-reflective (or radiant) barriers on (or below) surfaces oriented to the summer sun.
- Minimize the outside wall and roof area ratio of exterior surface to enclosed volume (Fig. 6).
- *Solar windows and walls* (winter) – Using the winter sun for heating a building through solar-oriented windows and walls is provided by a number of techniques:
 - Maximize reflectivity of ground and building surfaces outside windows facing the winter sun.
 - Shape and orient the building shell to maximize exposure to the winter sun.
 - Use high-capacitance thermal mass materials in the interior to store solar heat gain.
 - Use solar wall and roof collectors on equatorial-oriented faces.
 - Optimize the area of equatorial-facing glazing.
 - Use clerestory skylights for winter solar gain and natural illumination.
 - Provide solar-oriented interior zone for maximum solar heat gain, with solar control for shading in overheated periods (Fig. 7).
- *Indoor/outdoor rooms* (winter and summer) – Courtyards, covered patios, seasonally screened and glassed-in porches, greenhouses, atriums, and sun spaces can be located in the building plan for summer cooling and winter heating benefits:
 - Provide outdoor semi-protected areas for year-round climate moderation (Fig. 8).
- *Earth sheltering* (winter and summer) – Techniques such as banking earth against the walls of a building or covering the roof, or building a concrete floor on the ground, have a number of climatic advantages for thermal storage and damping temperature fluctuations (daily and seasonally), providing wind

Bioclimatic Design. Figure 4

Climate consultant display of the building bioclimatic chart for Albany, NY. Climate Consultant provides visual displays of the Building Bioclimatic Chart, along with a wide range of other climatic data analyses (Milne and Li [12]) Climate Consultant Web link <http://www.energy-design-tools.aud.ucla.edu/>

protection and reducing envelope heat loss or gain (winter and summer). These techniques are often referred to as earth-contact or earth-sheltering design:

- Use slab-on-grade construction for ground temperature heat exchange and thermal storage.
- Use earth-covered or sod roofs.
- Recess structure below grade or raise existing grade for earth sheltering (Fig. 9).
- *Thermally massive construction* (summer and winter) – Particularly effective in hot arid zones, or in more temperate zones with cold clear winters. Thermally massive construction provides a “thermal fly wheel.” Absorbing heat during the day from solar radiation and convection from

indoor air can create comfort if it is cooled at night, if necessary through nighttime ventilative cooling (if air temperatures fall within the comfort zone):

- Use high mass construction with outside insulation and nighttime ventilation techniques in summers.
- For selected climates (hot dry), select high-capacitance materials to dampen heat flow through the building envelope (Fig. 10).
- *Sun shading* (summer) – Because midday solar altitude angles are much higher in summer than in winter, it is possible to shade windows from the sun during the overheated summer period while allowing it to reach the window surfaces and spaces

Bioclimatic Design. Figure 5

Sea Ranch, California. Landscape planting, roof slopes, and fencing designed for wind protection. Esherick, Homsey, Dodge, and Davis, Architects and Planners with Lawrence Halprin, Landscape Architect

in winter. Providing summer sun shading does not need to conflict with winter solar heat gain:

- Minimize reflectivity of ground and building surfaces outside windows facing the summer sun.
- Use neighboring landforms, structures, or vegetation for shading the summer sun.
- Shape and orient the building shell to minimize exposure to the summer afternoon sun.
- Provide seasonally operable shading, including deciduous trees.
- *Natural ventilation* (summer and seasonal)—Natural ventilation is a simple concept by which to cool a building:
 - Shape and orient the building shell to maximize exposure to summer breezes.
 - Use an “open plan” interior to promote airflow.
 - Provide vertical airshafts to promote “thermal chimney” or stack-effect airflow.
 - Use double roof construction for ventilation within the building shell.
 - Orient door and window openings to facilitate natural ventilation from prevailing summer breezes.
 - Use wing walls, overhangs, and louvers to direct summer wind flow into the interiors.
 - Use louvered wall openings for maximum ventilation control.

- Use roof monitors for “stack-effect” ventilation (Fig. 11).

- *Plants and water* (summer) – Several techniques provide cooling by the use of plants and water near building surfaces for shading and evaporative cooling:

- Use planting next to building skin (provided it does not interfere with ventilation).
- Use roof spray or roof ponds for evaporative cooling.
- Use ground cover and planting for site cooling.
- Maximize on-site evaporative cooling (Fig. 12).

The Importance of Documenting Performance

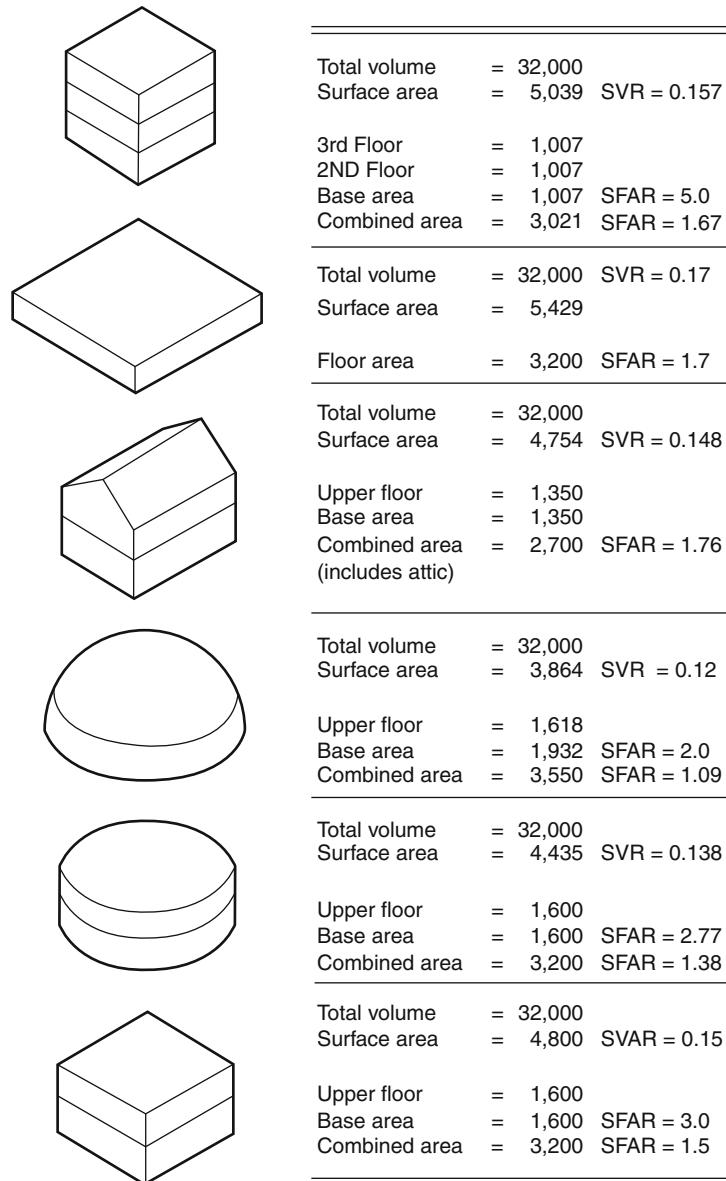

Simulation is a design tool, most appropriately used during the early design phases when alternate design techniques are considered. Simulation is not necessarily a means to predict actual performance. Design knowledge requires post-occupancy evaluation after a building is built and occupied.

To compare performance with predesign-simulated expectations requires careful monitoring of on-site weather conditions. Variations of use, user behavior, and factors as simple as how operating temperature controls are adjusted will account for greater variation than climate alone.

A post-occupancy survey was undertaken to assess 84 solar homes built with the assistance of a Solar Grant Program in Connecticut [14]. A grant of \$5,000 was offered to assist owners of existing homes to retrofit solar features, or, to incorporate into new construction. Solar features could include south-facing windows and skylights, thermal mass (Trombe wall), sunspace, and window insulation, as well as active solar domestic hot water systems. The survey asked what problems were notable after 1–5 years of occupancy, and of these what problems could be corrected and what could not (Table 3).

Bioclimatic Design of Atriums and Wintergardens

Atriums offer many energy design opportunities, depending upon climatic resources, to provide natural heating, cooling, lighting, and plants. It is necessary to establish clear design goals, defining the opportunities and liabilities of solar heating, natural cooling, and

Bioclimatic Design. Figure 6

Analysis of building aspect ratio. Simplified building shapes are compared for ratio of exterior surface to enclosed volume (Watson and Labs [13])

daylighting choices. Provisions for healthy planting and indoor gardens can be combined with atrium design, which enlarges the design criteria to include healthy conditions for plants as well as people.

The atrium concept of climate control has been used throughout the history of architecture and in indigenous building in all climates of the globe.

Suggested by its Latin meaning as “heart” or an open courtyard of a Roman house, the term “atrium” as used today is a protected courtyard or glazed winter garden placed within a building. Modern atrium design incorporates many architectural elements – wall enclosures, sun-oriented openings, shading and ventilation devices, and subtle means of modifying temperature

Bioclimatic Design. Figure 7

Solar windows walls. Keck + Keck, Architects developed solar design principles in the Chicago area in the 1930s. The solar home designs of Keck + Keck – in this example a prototype prefab homes for Green Ready-Built Homes – included large south-facing glass, exposed masonry floors with hypostyle (warm air radiant) heating, interior masonry walls, interior curtains, and exterior shading (Photo: William Keck, Architect)

Bioclimatic Design. Figure 8

Protected courtyard. Buli Khelam Ihakhang Monastery, Bhutan. In the Himalayan tradition of building, an enclosed courtyard with sun exposed adobe walls and windows creates a wind-protected microclimate, permitting a temperate planting regime to flourish within, in contrast to high mountain climatic conditions of its locale (Photo: Donald Watson)

and humidity – suggested by examples that derive from the courtyard designs of Roman, early Christian, and Islamic buildings, and the nineteenth-century greenhouses and glass-covered arcades of Great Britain and France.

Atriums offer many energy design opportunities: first, comfort is achieved by gradual transition from outside climate to building interior; second, designed properly, protected spaces and buffer zones create natural and free-flowing energy by reducing or by

(b) *Cross-section earth-covered home*. The cross-section of the earth-covered home was designed to provide balanced daylighting throughout the year, accomplished by light shelves and a clerestory light well

eliminating the need to otherwise heat, cool, or light building interiors. Depending on climatic resources and building use, the emphasis in atrium design has to be balanced between occupancy and comfort criteria and the relative need for heating, cooling, and/or lighting.

How the atrium can work as an energy-efficient modifier of climate is best seen by examining separately its potential for natural heating, cooling, and lighting. The first step is to establish a clear set of energy design goals appropriate to the specific atrium design. The resulting solution will depend upon its program

(whether for circulation only or for longer term and sedentary human comfort and/or for plant propagation and horticultural display) and the resulting environmental control requirements.

Bioclimatic Design. Figure 10

Solar Heating

If heating efficiency alone is the primary energy design goal of the atrium, the following design principles should be paramount:

H1 – To maximize winter solar heat gain, orient the atrium aperture (openings and glazing) to the equator. If possible, the glazing should be vertical or sloped not lower than a tilt angle equal to the local latitude.

H2 – To store and distribute heat, place interior masonry directly in the path of the winter sun. This is most useful if the heated wall or floor surface will in turn directly radiate to building occupants.

H3 – To prevent excessive nighttime heat loss, consider an insulating system for the glazing, such as insulating curtains or high performance multilayered window systems.

H4 – To recover the heat that rises by natural convection to the top of the atrium, place a return air duct high in the space, possibly augmenting its temperature by placing it directly in the sun. Heat recovery can be accomplished if the warm air is redistributed

Bioclimatic Design. Figure 11

Shading and ventilation strategies. Built in an era well before air-conditioning, plantation manor houses such as the 1827 San Francisco Plantation House, New Orleans, combined a range of strategies for natural cooling in hot humid climates zones, including open understory and porches, cross-ventilation, and roofs designed to induce ventilation by thermal updraft (Photo: Robert Perron)

Bioclimatic Design. Figure 12

either to the lower area of the atrium (a ceiling fan) or redirected (and cleaned) to the mechanical system, or through a heat exchanger if the air must be exhausted for health and air-quality reasons.

Because a large air volume must be heated, an atrium is not an efficient solar collector per se. But the high volume helps to make an overheated space acceptable, especially if the warmest air rises to the top. If the atrium is surrounded by buildings on all sides, direct winter sun is difficult if not impossible to capture except at the top of the skylight enclosure. However, by facing a large skylight and/or window opening toward the equator, direct winter solar heating becomes entirely feasible.

In cool climates, an atrium used as a solar heat collector would require as much winter sunlight as

Bioclimatic Design. Table 3 Extract from consumer survey of 84 solar homes (Watson [14])

possible. In overbright conditions, dark finishes on surfaces where the sun strikes will help reduce glare and also to store heat. On surfaces not in the direct sun, light finishes may be best to reflect light, especially welcomed under cloudy conditions. In most locations and uses, glass should be completely shaded from the summer sun. Although not practical for large atriums, in some applications greenhouse-type movable insulation might be considered to reduce nighttime heat loss.

Natural Cooling

Several guidelines related to the use of an atrium design as an intermediary or buffer zone apply to both heating and cooling. If an unconditioned atrium is located in a building interior, the heat loss is from the warmer surrounding spaces into the atrium. In buildings with large internal gains due to occupants, lighting, and machines, the atrium may require cooling throughout the year. If one were to design exclusively for cooling, the following principles would predominate:

- C1 – To minimize solar gain, provide shade for the summer sun. According to the particular building use, the local climate and the resulting balance point (the outside temperature below which heating is required); the “overheated” season when sun shading is needed may extend well into the autumn months. While fixed shading devices suffice for much of the summer period, movable shading is the only exact means by which to match the seasonal shading requirements at all times. In buildings in warm climates, sun shading may be needed throughout the year.
- C2 – To use the atrium as an exhaust air plenum in the mechanical system of the building. The great advantage is one of economy, but heat recovery options (discussed above) and ventilation become most effective when the natural airflow in the atrium is in the same direction and integrated with the mechanical system.
- C3 – To facilitate natural ventilation, create a vertical “chimney” effect by placing ventilating outlets high (preferably in the free-flow air stream well above the roof) and by providing cool “replacement air” inlets at the atrium bottom, with attention that the air stream is clean, that is, free of car exhaust or other pollutants.

The inlet air stream can be cooled naturally, such as accessed from a shaded area. In hot, dry climates, passing the inlet air over water such as an aerated fountain or landscape area is particularly effective to create evaporative cooling. Allowing the atrium to cool by ventilation at night is effective in climates where summer nighttime temperatures are lower than daytime (greater than 15°F difference), in which case the

cooling effect can be carried into the next day by materials such as masonry (although, as a rule, if the average daily temperature is above 78°F (25.5°C), thermally massive materials are disadvantageous in non-air-conditioned spaces because they do not cool as rapidly as a thermally light structure). The microclimatic dynamic is no different than that evident in the Indian tepee – when stack ventilation is possible through a roof aperture, the space will ventilate naturally even in the absence of outside breezes, by the driving force of heated air. If air-conditioning of the atrium is needed but can be restricted to the lower area of the space, it can be done reasonably; cold air, being heavier, will pool at the bottom.

While there is apparent conflict between the heating design principle to maximize solar gain and the cooling design principle to minimize it, the sun does cooperate by its change in its apparent solar position with respect to the building. There are, however, design choices to be balanced between the requirements for sun shading and those for daylighting. The ideal location for a sun shading screen is on the outside of the glazing, where it can be wind-cooled. When the outside air ranges about 80°F (26.7°C), glass areas – even if shaded – admit undesired heat gain by conduction. In truly warm climates, a minimum of glazed aperture should be used to prevent undesired heat gain, in which case the small amount of glazing should be placed where it is most effective for daylighting. Heat-absorbent or heat-reflective glass, the common solution to reduce solar heat gain, also reduces the illumination level and, if facing the equator, it also reduces desirable winter heat gain.

In temperate-to-cool climates, heat gain through a skylight can be tolerated if the space is high, so that heat builds up well above the occupancy zone and there is good ventilation. In hot climates, an atrium will perform better as an unconditioned space if it is a shaded but otherwise open courtyard.

Daylighting

In all climates, an atrium can be used for daylighting. Electric lighting cost savings can be achieved, but only if the daylighting system works, that is, if it replaces the use of artificial lighting. (Many daylit buildings end up

with the electric lights in full use regardless of lighting levels needed.) Atriums serve a particularly useful function in daylighting design for an entire building by balancing light levels – thus reducing brightness ratios – across the interior floors of a building. If, for example, an open office floor has a window wall on only one side, typically more electric lighting is required than would be required without natural lighting to reduce the brightness ratio. An atrium light court at the building interior could provide such balanced “two source” lighting. An atrium designed as a “lighting fixture” that reflects, directs, or diffuses sunlight can be one of the most pleasing means of controlling light.

The following principles apply to atrium design for daylighting:

- L1* – To maximize daylight, an atrium cross-section should be stepped open to the entire sky-dome in predominantly cloudy areas. In predominantly sunny sites, atrium geometry can be based upon heating and/or cooling solar orientation principles.
- L2* – To maximize light, window or skylight apertures should be designed for the predominant sky condition. If the predominant sky condition is cloudy and maximum daylight is required (as in a northern climate winter garden), consider clear glazing oriented to the entire sky-dome, with movable sun controls for sunny conditions. If the predominant sky condition is sunny, orient the glazing according to heating and/or cooling design requirements.
- L3* – Provide sun-and-glare control by geometry of aperture, surface treatment, color, and adjustable shades or curtains. Designing for daylighting involves compromise to meet widely varying sky conditions. What works in bright sunny conditions will not be adequate for cloudy conditions. An opaque overhang or louver, for example, may create particularly somber shadowing on a cloudy day. Light is already made diffuse by a cloudy sky, falling nearly equally from all directions; the sides of the atrium thus cast gray shadows on all sides. For predominantly cloudy conditions, a clear skylight is the right choice. Bright haze will nonetheless cause intolerable glare at least to a view upward. Under sunny conditions, the same skylight is the

least satisfactory choice because of overlighting and overheating. The designer's choice is to compromise. Unless the local climate is truly cloudy and the atrium requires high levels of illumination, partial skylighting can achieve a balance of natural lighting, heating, and cooling. Partial skylighting (i.e., a skylight design that occupies only a portion of the roof surface) offers the further advantage of controlling glare and sunlight by providing reflective and shady surfaces to the view, such as by the coffers of the skylights. Because it is reduced in light intensity and contrast, a surface illuminated by reflected light is far more acceptable to the human eye than a direct view of a bright window area. Movable shades for glare and sun control provide a further means of balancing for the variety of conditions. This can be provided simply by operable canvas or fiberglass shades.

The design principles for heating, cooling, and daylighting can be applied according to building type and local climate. In the northern climates, particularly for residential units or apartments that might be grouped around an atrium, the solar heating potential predominates, while the natural cooling potential predominates in the southern United States. In commercial and institutional structures, natural cooling and daylighting are both important. In this case, the local climate would determine the relative importance of openness achieved with large and clear skylighting (most appropriate for cloudy temperate-to-cool regions) or of closed and shaded skylighting (most appropriate for sunny warm regions). While no single recommendation fits any one climate, the relative importance of each of the design principles is keyed to different climatic regions in [Fig. 13](#).

Garden Atriums

Plants have an important role in buffer zones. If the requirements of plants are understood, healthy greenery can be incorporated into atrium design and contribute to human comfort, amenity, and energy conservation. Plants, however, when uncomfortable, cannot move. Major planting losses have been reported in gardened atriums because the bioclimatic

requirements were not achieved. A greenhouse for year-round crop or plant production is intended to create spring-summer or the growing-period climate throughout the year. A winter garden replicates spring-

summer conditions for plant growth in wintertime by maximizing winter daylight exposure and by solar heating. Plants need ample light but not excessive heat. Although it varies according to plant species, as

Bioclimatic Design. Figure 15

Large building opportunities for microclimatic design integration. Bioclimatic design extends to a larger scale and provides lower demand for integrated heating, cooling, and lighting systems (Watson [16])

a general rule planting areas require full overhead skylighting (essentially to simulate their indigenous growing condition). Most plants are overheated if their roots range above 65°F (18.3°C). Their growth slows when the root temperature drops below 45°F (7.2°C). As a result, a greenhouse has the general problem of overheating (as well as overlighting) during any sunny day and of underlighting (in intensity and duration) during any cloudy winter day.

If the function of the atrium includes plant propagation or horticultural exhibit (replicating the indigenous climate in which the display plants flower), then clear-glass skylighting is needed for the cloudy days and adjustable shading and overheating controls are needed for sunny days. If the plant beds are heated directly, by water piping, for example, then root temperatures can be maintained in the optimum range without heating the air. As a result, the air temperature in the atrium can be cool for people, in the 50°F (10°C) range, with the resulting advantage of providing a defense against superheating the space. People can be comfortable in lower air temperatures if exposed to the radiant warmth of the sun and/or if the radiant temperature of surrounding surfaces is correspondingly higher, that

is, ranging above 80°F (26.7°C). Lower atrium temperature offers a further advantage to plants and energy-efficient space operation because evaporation from plants is slowed, saving water and energy (1,000 Btu are removed from the sensible heat of the space with each pound of water that evaporates). Air movement aids plant growth, if gentle and pervasive. Air circulation reduces excessive moisture buildup at the plant leaf and circulates CO₂, needed during the daytime growth cycle. The requirements for healthy planting and indoor gardening can thus be combined with energy-efficient atrium design for benefit of both plants and people (Fig. 14).

Large-Scale Applications

Bioclimatic design principles and practices are not limited to small-scale buildings alone. The physical basis of passive heating and cooling dynamics are somewhat constrained to near-envelope zones, subject to dimension of spaces in and around the building perimeter. However, these can and should be integrated with larger scale mechanical strategies of air movement, preheating, and ventilation.

Daylighting techniques are scalable and can be applied to exterior envelope, skylighting, and atrium (light shaft) options. The history of buildings from the nineteenth century indicates possibilities, while improved glazing, shading, and insulation increase options for natural lighting that apply to large buildings.

Figure 15 diagrams the site and building opportunities for energy collection, storage, and distribution

that may be integrated as combined passive and active means of bioclimatic design.

Several publications document 1980s' and 1990s' applications of passive solar, daylighting, and related bioclimatic elements in larger-scale buildings. Burt Hill Kosar Rittelmann/Min Kantrowitz Associates [17], provides a summary report, including several years of performance data, post-occupancy evaluation, and user surveys of 20 medium- to large-scale buildings

assisted by the US Department of Energy Passive Solar Commercial Demonstration Grants. The grant program provided design and research assistance for building owners who had projects underway, but no so far advanced that they could not incorporate significant innovative approaches to energy conservation.

William M.C. Lam [18], provides a detailed discussion of sunlighting large buildings, including performance documentation of case studies and lessons learned. Several related projects involved faculty and students of Schools of Architecture in courses that undertake post-occupancy evaluations of completed buildings, monitoring all building energy, including air quality and daylighting, providing an archive of critical building assessments [19].

A number of current building designs at a large scale provide exemplary applications of microclimatic

design integration with heating, cooling, and lighting systems, with additional consideration of water and waste recycling. Such examples set standards for low energy and environmental impact, with relative value based upon building type and climate (Figs. 16 and 17).

Future Directions: Bioclimatic Design at the Urban Scale

Many studies address microclimatic impacts at the urban scale, described as “bioregional design” by the Olgyays [2]. Perennial topics have included solar access, evident in early twentieth-century studies related to daylighting and solar access for light and health, as well airflow and ventilation. Urban heat island effects have been addressed by studies of the effect of vegetation and “cool roofs.” The prospect of climate change and extreme weather has, in recent

Bioclimatic Design. Figure 18

years, added increased concern for design for resilience, mitigation, and adaptation to extreme weather, including flooding, drought, and increasing global warming. While full discussion of these topics is well beyond the scope of this entry, a few selected references indicate foundation studies and future directions.

Solar Access

Solar geometry. Studies by Ralph Knowles [20] undertaken over several decades with students at the University of Southern California have developed the notion

of assuring solar access to buildings, for sun tempering, daylighting, and solar collection. His studies have demonstrated that solar access can be guaranteed in most urban areas while keeping within conventional medium to medium-high density floor to area ratios (FARs) (all but very high rise districts) (Fig. 18).

Bioclimatic Data at the Urban Scale

Baruch Givoni [21] compiles a broad survey of urban bioclimatic data and design applications, with emphasis on measured data, along with

Bioclimatic Design. Figure 19

Pocket Park, New York City. Paley Park creates a small area of respite, with a cooling microclimate created by evaporative cooling, shading, and wind protection, while water fountain sound helps neutralize urban clamor (Photo: Donald Watson)

discussions of challenges of data measurement at the urban scale.

Table 4 shows averages of air and surface temperatures measured at a height of 1 m (3.3 ft.) around noontime on the UCLA campus during a sequence of several clear days in summer. The lowest temperatures were in a space between a line of high shrubs and a wall of a building.

Givoni's research and overview points to opportunities for continued research at the urban scale, supporting an approach to urban planning based on bioclimatic analysis and design (Fig. 19).

Urban Air Quality

Studies of wind at the urban scale have considered force of winds for structural and exterior envelope design, as

Bioclimatic Design. Figure 20

Wind tunnel. Smoke tracing helps to visualize wind effects of building form at the urban scale (Photo: Donald Watson)

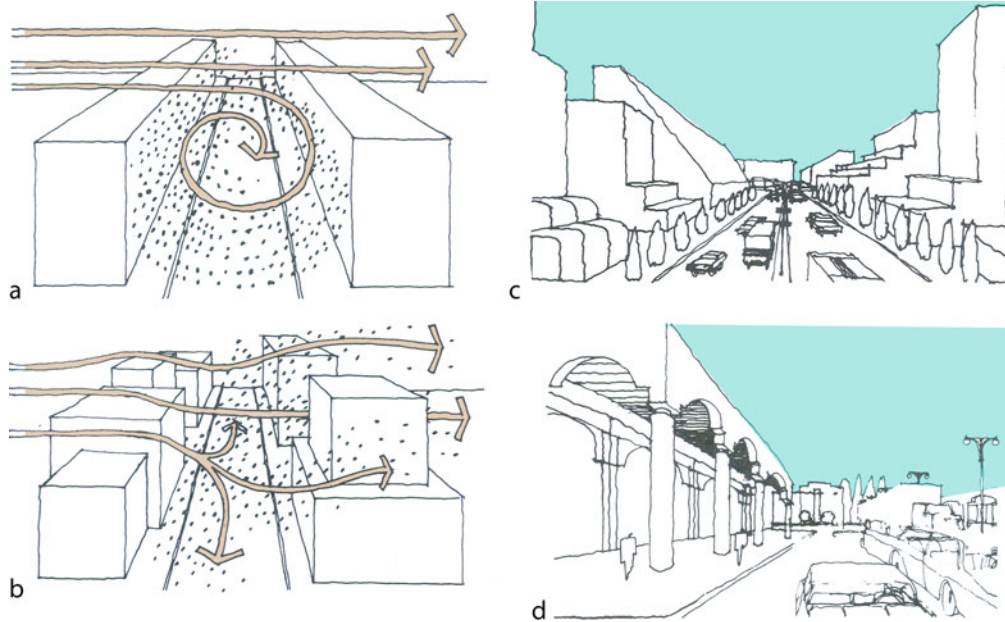

well as for wind tunnel (accelerating force of winds at constrained building openings), as well as aerodynamic shapes to induce natural ventilation. Models for such studies have included scaled wind tunnels, flow models, and full-scale mock-ups exposed to simulated wind forces (Fig. 20).

Studies by Anne Whiston Spirn [22] have utilized research on urban wind effects to propose design strategies to reduce pollution in city streets and public ways, principally by opening building forms to less constrained airflow (Figs. 21 and 22).

Resilience to Natural Disaster

Climate change is evident in global warming, extreme weather and storm events, flooding, and drought. The line of influence that climate had upon design is in a sense reversed. Design now influences climate in the way that buildings, infrastructure, cities, along with agricultural and industrial practices have in fact been executed without regard for bioclimatic impacts.

The natural landscape that has evolved in response to climate and water regimes over millennia had adapted to long-evolving patterns of rainfall, aridity, heat, and cold. Historical flood conditions were accommodated within the watershed ecology and its

Bioclimatic Design. Figure 21

Air Quality. The urban designer has opportunity to utilize strategies to improve air quality at the urban microclimatic scale. Anne WS. [22]. (a) – Street canyons lined with buildings of a similar height, oriented perpendicular to the wind direction tend to have poor air circulation compared to (b). (b) – Street canyons lined with buildings of different heights and interspersed with open areas have better air circulation. (c) – To promote air circulation in street canyons, step buildings back from the street, increase openings, and vary building heights. (d) – To promote air circulation in street side arcades, design them with high canopies and airflow outlets

coevolving plants and animals. When those patterns are disrupted and the natural landscape is altered, flooding risks and disasters increase, as much a result of human actions as natural occurrence.

While the prospect of sea level rise is undefined as to extent and time, the recent incidence of historically unprecedented natural disasters has impelled some nations and regions to undertake programs of adaptation and mitigation. The Netherlands has undertaken a 100-year plan to address flooding by an integrated and phased set of improvements to dykes, removals, and elevations of buildings in increased flood plains, and abandoning the most exposed risk area to natural recovery. In Japan, where spring flooding from mountains has resulted in flash floods in densely populated urban areas that have built up in floodplain areas, the range of actions also include “super-levees,” which essentially reconfigure land along river floodplain, while increasing floodable zones that can hold

floodwaters during peak floods, while making them available for temporary use at other times, easily evacuated in case of emergency (Fig. 23).

Watson and Adams [23], propose an extension of bioclimatic design to include design for resilience, to adopt precautionary principles in design of buildings, communities, and cities. Resiliency describes the capacity to respond to stress and change of climatic conditions. Resiliency is evident in natural systems in strategies to adjust to variable and extreme conditions. Characteristics of resilient systems include buffering, storage, redundancy, self-reliance, decentralization, diversity, energy conservation, rapid adaptability, and replacement (Table 5).

Summary

Bioclimatic design is based on the analysis of the climate, including ambient energy of sun, wind, temperature, and humidity. Bioclimatic design utilizes passive

Bioclimatic Design. Figure 22

Comprehensive plan to improve air quality. Stuttgart, Federal Republic of Germany. Public gardens and open space atop the cities hills and hillside canyons are preserved as vegetated public stairways and watercourses. The hillside canyons funnel cool nighttime airflow to center city streets and downtown parks (Photo courtesy of Dr. Michael Trieb, Urban Planning Institute, University of Stuttgart)

and ambient energy sources to achieve human comfort through building design and construction, including heating, cooling, and daylighting techniques. Derived from regional and local conditions and opportunities, bioclimatic analysis and design provide both a knowledge base and an inspiration for architecture and sustainable design.

Bioclimatic design analysis is a foundation step in architectural design, essential in the beginning phases to set design guidelines and goals, which can then be compared with actual performance results. By tracking performance results, a designer can thus gain knowledge of the effectiveness of bioclimatic design strategies and techniques for a particular locale and regional microclimates.

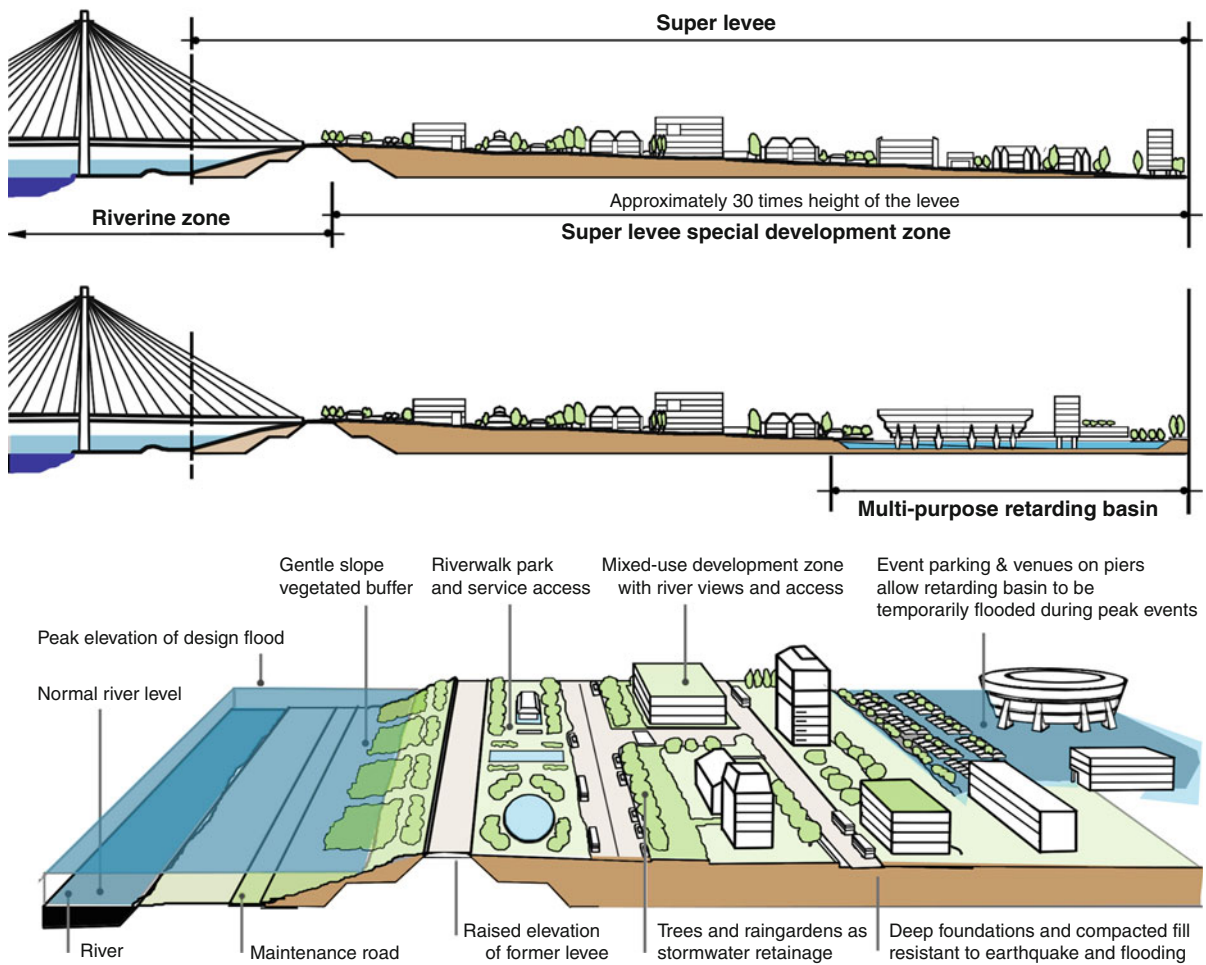

A present day challenge is climate change, which portends to increase the severity and period of warming, or overheated, conditions. Climate and weather uncertainty and warming trends should be anticipated in building design to be adaptive by a balance of techniques for heating and for cooling.

The challenge to reduce and eliminate where possible the use of fossil fuels for carbon reduction further supports the passive design strategies of bioclimatic design, for its combined advantages of comfort and health, environmental well-being, and resilience to extreme weather.

The enlargement of bioclimatic design to design for resilience is a necessary response to the increased severity of natural disaster. The science of building and urban climatology can fully inform steps to remediate flooding and other risks, so that the natural ecology of regions is returned to its role in moderating extremes and sustaining the diversity of species.

Glossary

Biodiesel Fatty acid methyl or ethyl esters made out of fatty acid material.

Catalyst Chemical compound that increases the reaction rate of a chemical reaction, either soluble (homogenous) or insoluble (heterogeneous).

BtL fuels Fuels made out of biomass by gasification and further synthesis with Fischer–Tropsch catalysts.

Esterification Chemical reaction of a carboxylic acid with an alcohol forming a carboxylic ester and water.

Feedstocks Any vegetable oil, animal fat, waste oils like used cooking oil, fatty acids.

Green house gas (GHG) savings Saving of the emissions of green house gases of a biofuel in the whole production chain in comparison to fossil fuel.

Life cycle analysis Assessment of the environmental impacts of a given product caused by its production and use.

Transesterification Chemical reaction of a carboxylic ester with an alcohol or a carboxylic acid in order to obtain another carboxylic ester.

Definition of the Subject and Its Importance

The transport sector is one the fastest growing segment using fossil-based products. Especially because of the economic development in countries like India and China, there is a need for high mobility and transport. Today's transport system is based on combustion engines using fossil fuels, leading to a sharp increase of emissions of green house gases (GHG) within the last decades. Furthermore, for most of the industrialized countries there is a strong dependency on oil-producing countries, which could cause political conflicts and even wars. Therefore, especially in times of a sharp increase in crude oil prices, the question of alternative fuels or transport systems is highly discussed. Moreover, the effects of global warming caused by the increased emissions of green house gases stimulate the call for alternative fuels. For kinds of energy like electricity and heating power, there are sufficient alternatives available like photovoltaics, wind energy, and biomass; in the transport sector, the alternatives are rare. Electric vehicles could be used in special segments of the transport sector like in urban areas, but due to the limited capacity of energy storage in batteries, these electrically powered cars could not substitute combustion engines in large extent within the next decades. For aviation fuels, there has not been any suitable alternative to kerosene. The use of alternatively produced hydrogen basically could power combustion engines as well as electric cars with fuel cells, but because of the high price and lack of infrastructure there would not be a market penetration within the next decade. So the only short-term alternative for the transport sector is the use of liquid biofuels, which are produced out of biomass and could be used in existing engines. Bio-ethanol is a well-established fuel for gasoline cars, starting with activities in Brazil in the 1970s, and biodiesel made out of fats and oils is an ideal alternative fuel for diesel engines, which are the only type of engine used in heavy-duty vehicles in the transport sector but also in large extent in passenger cars in Europe. Biofuels not only can substitute to a certain extent the high demand for fuels in the transport sector

and therefore lead to less dependency on fossil fuel imports, but also have an environmental effect in lowering local emissions of soot and particles and also global emissions of green house gases. Furthermore, the production of biofuels could also contribute to social welfare by increasing the employment in the agricultural and industrial sector. However, the sustainability of biofuels production and utilization has to be proven by life cycle assessment (LCA) and thorough evaluation of the social impacts.

Introduction

The main drivers for the fast development of biofuels in the last decade worldwide where on the one side the high dependence of most of the countries on imports of fossil fuels, and on the other side the need for reduction of green house gases.

Biodiesel today is the most popular biofuel besides bioethanol. Chemically, biodiesel is defined as fatty acid methyl or ethyl esters made out of vegetable oils or animal fats. Because of the limited availability of agricultural areas and because of the food versus fuel discussion in the last years, especially, waste oils like used frying oil or animal fat as well as microbial oils from microalgae are highly favored. But also other nonfood crops like *Jatropha curcas*, which could be also cultivated on marginal areas, are currently investigated. Other biofuels for diesel engines are pure vegetable oils or biomass to liquid fuels (BtL), made via gasification of biomass and Fischer–Tropsch synthesis. As most of the biodiesel today is used as blend with fossil fuel and the warranties of most of the engine manufacturers and fuel companies only are given up to a specific amount of conventional biodiesel in fossil fuel, also hydrogenation of vegetable oils to remove the oxygen leading to hydrocarbons, which could be mixed with biodiesel also in higher amounts, is a possible route. These fuels, which are called hydrogenated vegetable oils (HVO) or NExBtL fuels, will also come into the market within the next years.

In this entry, mainly conventional biodiesel, fatty acid methyl, and ethyl ester, will be covered in detail.

History of Biodiesel

The idea to use vegetable oils as fuels for diesel engines is more than 100 years old. As Knothe points out in

a review on the historical development of biofuel production, Rudolf Diesel himself, the inventor of the diesel engine, conducted engine tests on plant oils [1]. So one prototype of his new engine presented at the World's Exhibition in Paris in 1900 ran on peanut oil and did so quite smoothly, so that hardly any visitor was aware of the fact. The idea for this test had apparently stemmed from the French government, which was searching for a means of domestic fuel production in their African colonies. Several other European countries took up the idea, which resulted in a number of articles on the use of tropical oils as diesel fuels by Belgian, French, Italian, British, and German authors. However, as petroleum-based fuels soon became available in large quantities at comparatively low cost, interest in plant oils diminished. Except for some attempts at utilizing renewable sources of energy during the Second World War, it was only in the 1970s that the worldwide oil crises and a growing environmental awareness led to the rediscovery of plant oils as possible alternatives to hydrocarbon-based fuels. The urge to fight agricultural overproduction served as an additional incentive to this development. As neat vegetable oils can only be used in modified diesel engines because of their high viscosity compared to fossil fuel, chemical transformation of the vegetable oils is the matter of choice to adapt the fuel to existing engines.

Transesterification of vegetable oils with lower alcohols has turned out to be an ideal modification, so that the term “biodiesel” is now only used to denote products obtained by this technology. The reaction between triglycerides and lower alcohols, yielding free glycerol and the fatty acid esters of the respective alcohol, was first described in 1852 [2]. The first reference to fatty acid alkyl ester fuels stems from 1937. A Belgian patent on the production of palm oil ethyl esters by acid-catalyzed transesterification describes the first use of a fuel, which would now be referred to as “biodiesel” [3]. Only a year later, in the summer of 1938, a bus fueled with palm oil ethyl esters ran between Brussels and Louvain [4]. However, these pioneering efforts in utilizing transesterified vegetable oils seem to have petered out soon afterward.

After a break in the study of fatty acid alkyl ester fuels of about 40 years, the idea was taken up again at the beginning of the 1980s. The topic was discussed in several international conferences and reappeared in

scientific publications. Rapeseed oil methyl esters (RME) was being produced and its feasibility as a diesel fuel was first being tested at Graz University [5]. Also other teams in South Africa (1981), Germany, and New Zealand (1982) soon directed their research efforts to the production of biodiesel. Already in 1987, a small pilot plant in Silberberg, Austria, started its production of rapeseed oil methyl esters, based on an innovative low-pressure, low-temperature technology, which had been developed by Mittelbach et al. 1986 [6]. The first industrial production plant for RME followed in 1991 (Aschach/Donau, Austria), and in 1995 two large-scale industrial plants in Rouen, France, and Leer, Germany, documented the rapid growth of the young biodiesel industry. The term “biodiesel” itself seems to have been coined in a Chinese article [7]. The next use of the expression in the scientific literature is documented in 1991 [8] after which the number of articles on the topic increased exponentially.

Biodiesel Production and Utilization Worldwide

Within the last decade, biodiesel production worldwide has been expanded enormously. Almost in every country worldwide, there are biodiesel activities, either in research, or in production in pilot or industrial scale. The main reasons for this rapid development are on one side the relatively easy process for transesterification of vegetable oils, which could be done without major investments, and on the other side the easy and well-established utilization of this biofuel either as pure fuel or as various blends with fossil diesel without any modifications of the engine.

As it can be seen in Fig. 1, the world production of biodiesel in 2008 was 12.2 million tons, out of which 65% have been produced in the EU-27. According to Table 1, the leading country is Germany with a long tradition in biodiesel, followed by the USA, which mostly produced biodiesel for the export to Europe; however, this export has been reduced significantly in 2009 due to new legislation in Europe. Outside Europe, the major biodiesel producers are the soybean-producing countries, namely, the USA, Argentina, and Brazil. Within Europe, there is a big gap between biodiesel production capacity and actual biodiesel production, as can be seen in Table 2. There are several reasons for that fact: First of all the dramatic increase

Biodiesel. Figure 1

Biodiesel production 2008 EU-27 and worldwide

Biodiesel. Table 1 Ranking of the biodiesel-producing countries worldwide (Source: Argentine Biofuels Chamber [9])

	Country	Biodiesel production million tons in 2008
1.	Germany	2,819
2.	USA	2,327
3.	France	1,815
4.	Brazil	1,027
5.	Argentina	960
6.	Italy	595
7.	Malaysia	420
8.	Belgium	277
9.	Poland	275
10.	Portugal	268

in vegetable oil prices in 2008, which, however, stabilized in 2009, and the insecurity on the future of biofuels as long as the new European Energy Directive had not been finalized. Furthermore, especially in Germany the introduction of mineral oil tax for pure biodiesel almost totally shut down the use of pure biodiesel (B100).

Europe is still the biggest consumer of biodiesel, about 2 million tons of biodiesel are imported. Most of the biodiesel is used in blends with fossil diesel and regularly sold at filling stations as B5 or B7, which

Biodiesel. Table 2 Biodiesel production and capacity in EU (European Biodiesel Board [10])

Country	Production 2008	Capacity 2009
Germany	2,819	5,200
France	1,815	2,505
Italy	595	1,910
Belgium	277	705
Poland	275	580
Portugal	268	468
Denmark/Sweden	231	352
Austria	213	707
Spain	207	3,656
UK	192	609
Slovakia	146	247
Greece	107	715
Hungary	105	186
Czech Rep.	104	325
The Netherlands	101	1,036
Finland	85	340
Others	215	1,360
Total	7,755	20,909

means 5% respectively 7%/volume blended with fossil diesel. Higher blends today have not been accepted by most of the engine manufacturers, so to reach the European goals of 10% biofuels (on an energy base) in 2020 either other biofuels have to be introduced (BtL or hydrogenated vegetable oils) or higher blends have to be used in special market segments like agriculture and captive fleets.

Feedstock for Biodiesel Production

The main feedstocks for biodiesel production are still the most common vegetable oils like rapeseed oil (Canola) or soybean oil. All major seed oils have similar fatty acid distribution, so the properties of the biodiesel produced is also quite similar except the cold temperature behavior, which depends on the sum of total saturated fatty acids. According to Fig. 2 in Europe the dominating source is rapeseed oil, which is also the main vegetable oil produced. Rapeseed oil gives

Biodiesel. Figure 2

Feedstocks for biodiesel production in Europe, estimation for 2009 (USDA [11])

a biodiesel, which meets the European specification for biodiesel, EN 14214, and has the best cold temperature behavior from all common feedstock. On the second place, there is soybean oil, which is mainly imported as biodiesel from the USA and Argentina. Biodiesel from 100% soybean oil does not meet the EN 14214 specification because of the higher Iodine Number due to the higher content of linoleic acid, however, it can be used as blend with other feedstock.

One of the most important factors for the economy of biodiesel production is the price of feedstock. Rapeseed oil is the most expensive vegetable oil for biodiesel production, so most of the biodiesel producers have to blend rapeseed oil with a certain amount of other oils, for example, used frying oil or waste animal fat. However, the amount of these products is limited and due to the high demand of these sources also the price increased significantly. One of the cheapest vegetable oil is palm oil, which is mainly produced in Malaysia and Indonesia, but the amount as blending feedstock is limited due to the poor cold temperature behavior.

The world production of vegetable oils and animal fats today is about 150 million tons, out of which already 12 million tons are used as feedstock for biodiesel. As most of the vegetable oil and animal fat production is used for food purposes, the maximum amount for biodiesel production is limited if there would not be any significant increase in oil and fat production. Twelve million tons of biodiesel together with about 40 million tons of bioethanol worldwide substitute fossil transport fuel with approximately 1.3%. As diesel fuel is the major fuel in transportation, it can be seen easily that vegetable oils and fats alone

cannot substitute diesel fuel in a significant share. So new feedstocks, which do not necessarily require common agricultural areas, have to be found in order to meet the high demand for biobased diesel fuel. High expectations were put into BtL (biomass to liquid fuels) production from lignocellulosic feedstock, so-called second-generation fuels, which however were not fulfilled until today because of high development and investment costs for such technology. Only one production plant in Freiberg, Germany (CHOREN), exists today, which until mid-2010 has not been put into standard operation. Other technologies like hydrogenated vegetable oils require the same feedstock as common biodiesel, so this route will not lead to higher amounts of biodiesel.

Promising feedstock in mid-term or long-term perspective are nonfood feedstock like *Jatropha curcas* L., which can be also grown on marginal areas or oils from microalgae that can be grown in open ponds or photobioreactors.

Nonedible Oils as Feedstock for Biodiesel Production

Out of the enormous potential of possible nonedible seeds, *J. curcas* as example will be described in detail to show the potential and risks of nonfood feedstock.

J. curcas has shown to be the most promising nonedible crop for biofuel production. This can be seen on the one side on the number of international *Jatropha* conferences organized during the last decade, and on the other side on the increasing number of scientific publications, which are dealing with research on *Jatropha* as alternative feedstock (Fig. 3).

The first activities in the exploration of *J. curcas* as possible feedstock for biodiesel production has been carried out within the Biomass Project in Nicaragua between 1990 and 2000, financed by the Austrian government. Within that project, a total area of 1,000 ha of *J. curcas* had been planted, and also a biodiesel plant has been installed, which however, never went into operation. One highlight of the project was the organization of the first international conference on *J. curcas* in Managua in 1997. The proceedings of that conference covered the whole spectrum of *J. curcas* knowledge at that time [13]. However, the whole project was stopped according to an external evaluation coming to the conclusion: "The biofuel part, however, suffers from the development of fossil fuel prices, which makes the production of diesel from physic nut uneconomic at the moment."

The most influencing factor for the total economic evaluation of *J. curcas* utilization is the use of the side product oil cake, which would bring the most benefit if

Biodiesel. Figure 3

Number of scientific publications on *Jatropha* according to SciFinder, CAS [12]

it could be used as animal feed. However, due to the remaining highly toxic phorbol esters in the oil cake the use as animal feed is not possible without any efficient detoxification. So today, the only possible utilization of oil cake would be the use as fertilizer, which, however, is far less profitable than the use as animal feed.

The main advantages of *J. curcas* over other food crops can be summarized in the following:

- Wide distribution in the tropics
- Good adaptation to marginal areas, poor soil
- Best adaptation to arid and semiarid conditions
- Easy agronomic handling
- No competition with food crops due to the content of toxic compounds
- High oil content in the seeds: up to 55% (dehulled)

On the other side, there are some drawbacks of *J. curcas* like the following:

- High yields need intensive agricultural production (water, fertilizer, pest control)
- Toxic seeds have to be processed in specified plants
- The use of side products like seed cake and glycerol is limited
- Harvesting is laborious, long harvesting period
- The actual yield of seeds per ha is lower than expected

One main disadvantage can be seen in the laborious harvesting, which today has to be done manually. On the one side, this fact is seen positively because the laborious harvesting could bring income to people living in rural areas, on the other side the total economy of *J. curcas* is mainly influenced by the costs of labor, which could increase rapidly. The advantage to use a nonedible crop could easily change into a disadvantage, if the utilization of side products like oil cake and glycerol is limited and less economic.

The main strategies to overcome these problems could be either the use of nontoxic varieties like some Mexican species or the detoxification of side products in order to get higher value-added products.

It can be seen that countries like China and India, where the use of food products for biofuel production is not accepted, have the greatest interest in nonedible plants like *Jatropha*. It is quite obvious that the utilization of *Jatropha* should not be focused on biofuels alone, but should include all other parts of the plants

as well as the side products of biodiesel production. Especially in China, there is a big interest in the utilization of the biologically active components in the different parts of the plant. Also the extraction of phorbol esters out of the oil and further utilization of these products is of great importance. Especially high value-added minor components and side products could improve the overall economy of *Jatropha* production and could overcome the high costs of labor-intensive manual harvesting. The use of nontoxic varieties like some species from Mexico might be challenging and attractive, however, also the possible risks have to be considered. Within a global market for seeds and oil, the coexistence between nontoxic and toxic varieties might be a high risk, especially if nontoxic oil and oil cake are considered as potential food and feed. Special certification, labeling, and control systems have to be established in order to avoid serious accidents with dramatic consequences for the whole business.

In mid-term future, the use of toxic *Jatropha* varieties will be favored, especially because of already established large investments in classical *Jatropha* plantations in a series of areas like Africa, India, Indonesia, and China. However, research in nontoxic varieties has to be carried out in order to evaluate the potential of these varieties for food and feed production. The focus for the utilization of toxic varieties will be the detoxification of the oil in order to obtain additional high value-added products, and the detoxification of the oil cake in order to get a nontoxic animal feed.

Within the last years, a significant number on reviews on *J. curcas* have been published worldwide. In two recent reviews, the latest developments in agronomy, oil production, alkyl ester production, toxicity, plant breeding, and crop expansion of *J. curcas* are discussed [14, 15]. The seeds of the plant are not only a source of biodiesel but also contain several metabolites of pharmaceutical importance. Common exploitation for biopharmaceuticals and bioenergy production are some of the prospective future potential of this plant [16, 17].

A series of publications are dealing with the detoxification of either *Jatropha* oil and/or oil cake mainly focusing on the degradation of the highly toxic phorbol esters in order to use the oil cake as

animal feed [18, 19]. However, no technically feasible method has been developed so far to totally detoxify the seed cake for safe use as an animal feed.

Potential of Microalgae as Feedstock for Biodiesel

Because of the food versus fuel discussion within the last years, microalgae as potential feedstock for biofuel production has been discussed widely around the world. High expectations have been set into this kind of biomass, because no agricultural areas are necessary for cultivation and additionally green algae need CO₂ as carbon source, which could be taken out of flue gases from power stations and could help to reduce overall green house gases.

Almost 30 years ago, the US department of energy had launched a program studying the potential of microalgae as biofuel, but the program was stopped in 1996 due to the high production costs compared to the low fossil fuel prices.

Microalgae include a variety of photosynthetic microorganisms capable of fixing CO₂ from the atmosphere to produce biomass more efficiently and rapidly than terrestrial plants; algae require approximately 2 g of CO₂ for every g biomass generated [20]. The estimated productivity lie between 10 and 50 g/m² and day, the oil content lies between 15% and 50%, so a daily overall production of 15–250 kg oil/ha could be calculated. A dry biomass yield between 73 and 350 t/ha and year is estimated, depending on a photosynthetic conversion efficiency between 2.1% and 10% [21].

However, all these data are based on the assumption, that the extracted oil mainly consists of triglycerides, which easily could be converted into well-established biodiesel. However, it has been shown, that the content of triglycerides can vary widely, and a series of non-triglyceride material like hydrocarbons and terpenes can be found in the extractable oil mixture. Furthermore, there is a series of technical questions, which have to be solved and which make the production of algae for fuels today totally uneconomic. The choice of microalgae out of thousands of different species, the cultivation method like open ponds or photo-bioreactors, the harvesting, extraction of oil, and further processing are some of the challenges that have to be faced. Today the cultivation of algae only makes sense as

integrated approach in a biorefinery, where valuable products like ω -3 fatty acids or carotenoids are produced and could be sold as nutraceuticals, proteins could be separated and used as animal feed, and the remaining biomass could be used for biofuel production.

So all in all microalgae could have a large potential for biofuel production in long-term perspectives, however, a lot of research is still necessary and the crude oil price must rise significantly in order to make the algae cultivation and processing for biofuels competitive.

Biodiesel Production Technologies

As it can be seen in Fig. 4, the number of publications and patents dealing with biodiesel has increased enormously within the last 10 years. Especially the number of patents on biodiesel production technology per year has reached over 500. A lot of new innovations regarding new types of catalysts, new purification and refinement steps, separation techniques, and new feedstock have been developed.

Chemically, biodiesel is equivalent to fatty acid methyl esters or ethyl esters, produced out of triacylglycerols via transesterification or out of fatty acids via esterification. In Fig. 5 the formula scheme for the production of fatty acid mono alkyl esters out of triacylglycerol is shown. Fatty acid methyl esters today are the most commonly used biodiesel species, whereas fatty acid ethyl esters (FAEE) so far have been only produced in laboratory or pilot scale.

As vegetable oils or animal fats mainly consist of triacylglycerol (triglycerides) the main reaction for the production of biodiesel is the transesterification or alcoholysis reaction (Fig. 5), whereas esterification is only necessary for feedstock with higher content of free fatty acids.

In a transesterification or alcoholysis reaction, 1 mole of triglyceride reacts with 3 moles of alcohol to form 1 mole of glycerol and 3 moles of the respective fatty acid alkyl ester. The process is a sequence of three reversible reactions, in which the triglyceride molecule is converted step by step into diglyceride, monoglyceride, and glycerol. In order to shift the equilibrium to the right, methanol is added in an excess over the stoichiometric amount in most commercial biodiesel

Biodiesel. Figure 4

Number of scientific publications on "Biodiesel" according to SciFinder, CAS [12]

Biodiesel. Figure 5

Production of fatty acid mono alkyl esters via transesterification

production plants. A main advantage of methanolysis under alkaline catalysis is the fact that the two main products, glycerol and fatty acid methyl esters (FAME), are hardly miscible and thus form separate phases – an upper ester phase and a lower glycerol phase. This process removes glycerol from the reaction mixture and enables high conversion. Ester yields can even be increased – while at the same time minimizing the excess amount of methanol – by conducting methanolysis in two or three steps. Here, only

a portion of the total alcohol volume required is added in each step, and the glycerol phase produced is separated after each process stage.

Catalysts for Transesterification and Esterification Reactions

Alkaline or basic compounds are by far the most commonly used catalysts for biodiesel production. The main advantage of this kind of catalysis over acid-catalyzed transesterifications is the high conversion

rate under mild conditions in comparatively short reaction times [22]. However, free fatty acids as minor components in unrefined oils, are converted into soaps and are separated together with the glycerine phase. So the maximum conversion rate depends on the quantity of glycerides in the feedstock. For oils with higher amounts of free fatty acids, a combination of an acidic esterification of free fatty acids and an alkaline transesterification lead to a conversion of almost 100% of fatty acid material. With oils up to 3% of free fatty acid content, the combination of an alkaline transesterification and a post-esterification of the fatty acids recovered out of the glycerol phase is an optimum solution [23]. Also a pre-esterification under acidic catalysis prior to an alkaline transesterification leads to high conversion rates. Concentrated sulfuric acid can be used as cheap catalyst, but this can lead to losses due to the formation of side products, so also heterogeneous catalysts like ion exchange resins can be used [24].

As alkaline catalysts for transesterification mostly sodium or potassium hydroxide or alcoholates are used. In small- or medium-scale biodiesel production plants, the use of cheaper alkali hydroxides are preferred, however, there is the need of special equipment for dissolving the solid catalyst in methanol. As these homogeneous catalysts can only be used once, they remain as salts in the glycerol phase. For the production of raw or pharmaceutical grade glycerol, the glycerol phase has to be neutralized with an acid, and the formed alkali salts either remain in the raw glycerol or can be filtered off. If sodium hydroxide is used as catalysts, these salts are special waste and have to be disposed, whereas in the case of potassium hydroxide these salts can be reused as fertilizer. For biodiesel production in huge industrial size production plants with a capacity of 100,000 t/year or more mostly refined vegetable oils are used, which at least have to be degummed and deacidified. In this case, the use of a solution of sodium methoxide in methanol is used as catalyst. Sodium methoxide is more expensive than hydroxides, but if refined oils are used as feedstock, less catalyst can be used and the formation of soaps as side products is minimized.

Whereas traditional homogeneous catalysis offers a series of advantages, the major drawback is the fact that homogeneous catalysts cannot be reused. Moreover, catalyst residues have to be removed from the

ester product, usually with several washing steps, which increases production costs. Thus, there have been various attempts at simplifying product purification by applying heterogeneous catalysts, which can be recovered by filtration or are alternatively used as fixed-bed in continuous operation. The most frequently cited heterogeneous alkaline catalysts are alkali metal- and alkaline earth metal carbonates and oxides [25].

The main disadvantage of heterogeneous catalysis is the need for drastic reaction conditions like high temperature and pressure, which leads to higher investment costs and to higher operating compared to homogeneous catalysis. Also higher reaction temperature facilitates the formation of side products. On the other side, most of the heterogeneous catalysts can be reused for a specific time and also most of these catalysts can be used simultaneously for esterification and transesterification [26, 27]. The first technology using heterogeneous catalysts like zinc oxides or zinc aluminates is used in several commercial biodiesel production plants in France and in the USA [28, 29]. The so-called Esterfip-H process was developed by the Institut Français du Pétrole (IFP) and is designed and commercialized by Axens. The main advantages of the process are described as the production of high-quality glycerol and no need for disposal of salts resulting from the catalyst. However, the overall economic advantages have to be proved in long-term running.

Within the last years, the use of enzymes as heterogeneous catalysts for the production of biodiesel has been described widely in literature [29]. Lipases are enzymes that catalyze both the hydrolytic cleavage and the synthesis of ester bonds in glycerol esters. Their application in FAME production dates back to Choo and Ong [30], filing a patent application on lipase-catalyzed methanolysis in the presence of water, and to Mittelbach, reporting on the first water-free process for lipase-catalyzed biodiesel production [31]. As compared to other catalyst types, biocatalysts have several advantages. They enable conversion under mild temperature-, pressure-, and pH-conditions. Neither the ester product nor the glycerol phase has to be purified from basic catalyst residues or soaps. Moreover, both the transesterification of triglycerides and the esterification of free fatty acids occur in one process step. As a consequence, also highly acidic fatty materials, such as palm oil or waste oils, can be used without

pretreatment. Furthermore, enzymes could be perfectly used for the production of fatty acid ethyl esters using azeotropic technical ethanol. Though the use of enzymes seems to overcome most of the problems related to biodiesel production, the major drawback is still the price of enzymes for the production of bulk chemicals. Therefore, the enzymatic route for biodiesel production today is still too expensive for industrial application.

Basically, transesterification of triglycerides with lower alcohols also proceeds in the absence of a catalyst, provided reaction temperatures and pressures are high enough [32–34]. Above the critical temperature, a gas cannot be liquefied. The supercritical conditions show liquid as well as gaseous properties, so there have been a lot of applications for CO₂ extractions but also for carrying out chemical reactions. The advantages of not using a catalyst for transesterification are that high-purity esters and soap-free glycerol are produced. The high excess of methanol, which has to be used during supercritical transesterification, seems to make the process not economically feasible; however, a two-step process has been described, which in the first step hydrolyzes the glycerides into fatty acid with an excess of water, and in the second step esterification takes place, which requires lower amounts of methanol [35].

Though non-catalytical hydrolysis of vegetable oils today is common practice in industrial application of the production of fatty acids, the non-catalytical production of fatty acid methyl or ethyl esters has not yet been commercialized. The main reasons are the high investment costs for the high temperature and pressure procedure, and also the possibility of side reactions, which lead automatically to lower yields and higher purification costs.

A series of other approaches for biodiesel production have been reported including membrane technology for separating of methanol and glycerol from biodiesel [36], ultrasound-assisted esterification and transesterification [37], microwave-induced reactions [38], the use of different solvents for faster reaction rates [39] as well as the so-called in situ preparation of biodiesel directly from oil containing biomass have been described [40]. All these technologies seem to be very challenging and innovative, however, no practical industrial application has been reached so far mainly

due to the higher investment or running costs compared to classical technology. However, all these approaches might be interested in the future in order to improve the whole life cycle assessment of the production of biodiesel in order to meet the high demands of international legislations for sustainable production.

Biodiesel Quality and Specifications

One prerequisite for marketing an alternative fuel is the existence of specifications, which of course are based on existing specifications for mineral-based products. Biodiesel has been commercially produced since almost 20 years starting with the first industrial scale production plants in Austria and Germany in 1991. As Austria was pioneer in biodiesel production and utilization, as early as in 1991 the first national specification for biodiesel worldwide was established. This standard was based on several years of experiments with biodiesel prepared from rapeseed oil. Three years later also in Germany, national standards were established, followed by Italy and France. Because of the rapid development of biodiesel utilization in Europe there was the need for a harmonized European Specification for biodiesel. After several years of intensive negotiations and discussions in CEN committees, the harmonized European specification for biodiesel used as 100% fuel or as blend component EN 14214 came effective in 2004 [41]. In 2001, also the US standardization body ASTM published the specifications ASTM D 6751 for pure biodiesel (B100) and for blending with fossil diesel in levels up to 20% by volume [42]. The different parameters can be divided into general parameters also valid for fossil fuel and biodiesel specific parameters, which have to be added because of the different chemical composition.

In Table 4, a comparison of general and biodiesel specific parameters and limits between the latest ASTM D 6751 and EN 14214 versions is given, based on the most recent developments.

As can be seen in Table 3, the different parameters and limits between CEN and ASTM standards for biodiesel are quite similar, however there are some differences, which can be seen as barrier for international biodiesel market. Especially the limitation for Iodine Number in the European Specifications excludes

Biodiesel. Table 3 Comparison of parameters and limits in European and US specifications

Parameter	Unit	EN 14214 [2008]	ASTM D 6751 09-a
Density	15°C [kg/m ³]	860–900	–
Viscosity	40°C [mm ² /s]	3.5–5	1.9–6
Flash point	[°C]	≥101	≥93
Sulfur	[mg/kg]	≤10	≤15
Sulfated ash	[% m/m]	≤0.02	≤0.02
Conradson carbon Residue	[% m/m]	≤0.30 (10% distil. residue)	≤0.05
Cetane number	–	≥51	≥47
Water	[mg/kg]	≤500	0.05 vol%
Total contamination	[mg/kg]	≤24	–
Copper corrosion	–	Class 1	–
Oxidation stability	[h]	≥6	≥3
Acid number	[mg KOH/g]	≤0.50	≤0.50
Distillation, T90	[°C]	–	≤360
Iodine number	[g Iodine/100 g]	≤120	–
Linolenic acid	[% m/m]	≤12	–
Polyunsaturated fatty acids (>4 double bonds)	[% m/m]	≤1	–
Methanol	[% m/m]	≤0.20	≤0.20
Monoglycerides	[% m/m]	≤0.80	–
Diglycerides	[% m/m]	≤0.20	–
Triglycerides	[% m/m]	≤0.20	–
Free glycerol	[% m/m]	≤0.02	≤0.020
Total glycerol	[% m/m]	≤0.25	≤0.250
Sum of Na, K	[mg/kg]	≤5	≤5
Sum of Ca, Mg	[mg/kg]	≤5	–
Phosphorus	[mg/kg]	≤4	≤10

biodiesel made from 100% soybean oil. However, it is allowed to blend different feedstock to reach the limits. Also there are some stricter European regulations for the oxidation stability and also for the limits of phosphorus as well as for calcium and magnesium.

The European as well as the US specifications have been the basis for a series of similar specifications in many countries around the world, so all in all there are quite similar regulations worldwide. However, these limits for different parameters are only

technically based, in order to reach a sustainable biodiesel production. A lot of additional regulations have been discussed worldwide and are outlined within the next chapter.

Environmental Issues of Biodiesel

Engine Emissions

The diesel engine, also called compression ignition engine (CI), was patented by Rudolf Diesel in 1892.

Biodiesel. Table 4 Relative emissions from rapeseed oil biodiesel compared to fossil diesel (without catalytical converter) (From Mittelbach and Remschmidt, Biodiesel, the comprehensive handbook)

Reference	CO	HC	NO _x	PM
Mittelbach et al. [49]	−4%	−20%	+28%	−23%
Vellguth [50]	−8%	−20%	+7%	Soot number: −45%
Apfelbeck and Gessner [51]	−10%	−36%	+4%	−31%
Scharmer et al. [52]	±0%	−20 to −40%	−	Up to 40% lower
Krahl, Prieger et al. [53]	±0%	−10 to −20%	+10%	Up to 40% lower
Sharp [54]	−39%	−70%	+3%	−25%
May et al. [55]	−10%	−20%	+10%	−50%
Goerke [56]	−41%	−49%	+12%	−41%
Sams [57]	−16%	−33%	+4%	+11%
Krahl, Munack et al. [58]	−37%	−22%	+10%	−10%
	−39% ^a	−20%	+28%	+60%
Makareviciene and Janulis [59]	−6%	−74%	+10%	Smoke density: −68%

Unlike the spark-ignited gasoline engine, Diesel's invention works on self-ignition. Diesel engines offer a series of advantages over their gasoline-fueled counterparts. So they operate at higher compression ratios than Otto engines, which improve energy efficiency. Moreover, the fuel-to-air ratio varies with engine load and therefore with the quantity of fuel injected, resulting in lean fuel–air mixtures. This has positive effects on carbon monoxide (CO) and hydrocarbon (HC) emissions. Drawbacks of the diesel technology include a tendency for increased nitrogen oxide (NO_x) and particulate matter (PM) emissions. Moreover, diesel engines tend to be heavier than comparable gasoline engines.

With direct (DI) and indirect (IDI) injection engines, two types of combustion systems have been developed. In the first fuel is injected directly into the combustion chamber, whereas in the latter fuel is injected into a pre-chamber, from which partially oxidized gases and evaporated fuel are introduced into the main combustion chamber. Although characterized by a comparatively harsh combustion noise, DI engines are now commonly used for passenger cars due to their low fuel consumption [43, 44]. This is done at the expense of slightly increased NO_x emissions for DI engines [45].

However, modern, electronically controlled injection systems, such as the “common-rail-system,” enable a compromise between conflicting interests [46].

The major part of combustion engine exhaust streams consists of the nontoxic components nitrogen, carbon dioxide, and water. However, about 1.4% of gasoline engine exhaust and 0.2% of diesel engine exhaust are composed of more or less harmful substances. The maximum amounts of certain pollutants in exhaust gases are regulated by national authorities in various countries throughout the world. In the European Union and the USA, these limited emissions are:

- Carbon monoxide, CO
- Hydrocarbons HC, resulting from unburnt or partially burnt fuel and lubricating oil compounds. Hydrocarbons are either regulated as total hydrocarbon emissions (THC) or as non-methane hydrocarbons (NMHC).
- Nitrogen oxides NO_x, including NO, which is produced in the engine, and NO₂, which results from NO through oxidation within the exhaust stream or later in the atmosphere. Other oxides, such as N₂O, which may also be present in the exhaust gas, are not regulated. Sometimes one

combined limit for HC and NO_x is used instead of two separate limits.

- Particulate matter, which is only regulated for diesel engines.

Carbon dioxide emissions today are not limited, but due to European regulations the overall average CO₂ emissions of a fleet from a car manufacturer should not exceed 130 g/km, starting from 2012 [47].

An enormous amount of data on measurements of legally limited exhaust components all over the world is available. In comparing these results, however, some points have to be kept in mind. First, exhaust emissions differ widely according to engine types, test cycles, and fuel grades used, so that a comparison of absolute pollutant concentrations derived from different sources hardly makes sense. Instead only relative emission changes between biodiesel from rapeseed oil and fossil diesel fuels are listed in Table 4. Second, emission values are greatly influenced by the application of an exhaust gas after treatment system. To demonstrate the effects of the fuels, only data without oxidation catalytic converters are listed. As it can be seen, literature data indicate an overall slight reduction of CO and a significant reduction of HC and particulate matter emissions, whereas NO_x emissions are slightly increased. The reason for the increase of NO_x emissions with biodiesel or biodiesel blends is not yet fully understood. Especially in newer types of heavy-duty engines, the increase of NO_x emissions is rather low. An assessment of North American heavy-duty engine emission test results for biodiesel from 49 experimental studies, including both engine dynamometer and vehicle test results, shows that the use of a common biodiesel blend (B20) consistently reduces emissions of particulate matter, hydrocarbons, and carbon monoxide by 10–20%. Especially for newer types of engines, there is no statistical evidence that the average NO_x emissions increase [48].

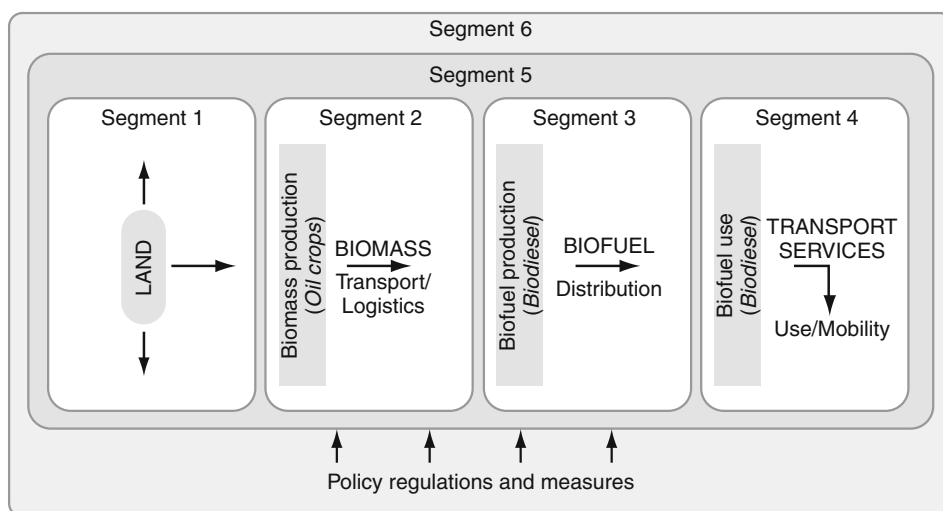

All these differences, however, will become irrelevant because of the future legislation for mandatory installation of efficient after treatment systems including particulate filters and SCR (selective catalytic reduction) technology.

Sustainability of Biodiesel

In the very first beginning of biodiesel development and utilization, no broad discussion has been taken

place on the issue, that agricultural products are used for fuel production. Especially because of rising oil prices and overproduction of agricultural products in Europe, biodiesel produced out of vegetable oils was a well-accepted alternative supported by some governments. There have been plans that biodiesel should mainly be used for agricultural production, ensuring the food supply in times of crisis. Furthermore, biodiesel production should bring a secure and continuous income for farmers, leading to a higher job rate in rural areas. However, biodiesel production was more and more industrialized, and a huge number of industrial biodiesel plants have been installed within the last 10 years around the world. The main driver was the need for the reduction of the green house gas emissions in the transport sector, leading to a number of incentives and mandates especially in Europe for the use of biofuels. The European Directive on the promotion of the use of biofuels or other renewable fuels for transport from 2003, mandating a share of biofuels in the transport sector of 5.75% until 2010 [60], led to an enormous boom of biodiesel production installations. Since 2008, however, when there has been the enormous rise in crude oil and food prices as well as in all other commodities, the fuel versus food discussion became fully effective. The consequence of this debate was the development of sustainability criteria and the assessment of the full life cycle analysis for all different biofuels. A lot of these sustainability criteria were included in the new European directive on the promotion of the use of energy from renewable sources from 2008, mandating a 10% share of biofuels in all countries of the European Union until 2020 [61].

Basically, biodiesel as renewable biofuel is considered as environmentally friendly because of saving CO₂ emissions by absorbing CO₂ during the growth of biomass [62]. However, by considering the whole life cycle of biofuels or biodiesel from production of the biomass until the final end use as fuel there are not necessarily environmental advantages. All the energy used for the whole supply chain including cultivation, the use of fertilizers and pesticides, harvesting, processing, and transport has to be considered (Fig. 6). Also the side effects of cultivation, above all the use of fertilizers producing the highly active green house gas nitrous oxide N₂O (300 times more effective

Biodiesel. Figure 6

Biodiesel supply chain (from well to wheel) [62]

than CO₂) have to be included. Furthermore, aspects of the use of ecological sensitive areas, as well as effects of direct and indirect land use change, have to be taken into consideration. Direct land use change (DLUC) concerns the case where production of energy crops for biofuels production leads to the conversion of land actually storing carbon-like grassland into cultivated land. This could lead to an overestimation of reduction of green house gases or in the case of degraded soil it could improve the soil carbon balance. Indirect land use change (ILUC) relates to the unintended consequence of releasing more carbon emissions due to land use changes around the world induced by the expansion of croplands for biofuel production. However, in most LCA studies ILUC is not considered, because more research is needed for harmonizing and improving the methodology.

Although there is a tool for the evaluation of the life cycle assessment existing in form of an ISO standard [63], it has been applied in literature in a variety of ways and thus often leads to diverging results. LCA is often limited to energy balance or to green house gas saving balance. Several LCA studies have been carried out under various frameworks, scopes, and consistency, making it difficult to compare the results [64]. One of the most important elements is to define the system boundaries, all individual processes of the complete life

cycle have to be considered, and also all coproducts have to be taken into consideration, especially glycerol and protein as oil cake. In the so-called allocation procedure, the environmental implications of a product and its coproducts are split, whereas in the substitution procedure the desired product gets a credit, which corresponds to the environmental implications of an equivalent product [65]. The issue of allocation is one of the weaknesses of biofuels LCA.

A much simpler approach is the calculation of the energy balance, which means the ratio between the energy of biofuel produced in the engine and the total energy needed for the total production of the biofuel without considering the solar energy for the growing of the biomass. For the main feedstock rapeseed oil and soybean oil in all published data there is a positive energy balance, which means the total energy input is lower than the output. The corresponding factors for rapeseed oil lie between 1:2 and 1:3 (input:output) and for soybean oil between 1:3.2 and 1:3.5 (from *Biodiesel – The Comprehensive Handbook*). For palm biodiesel a ratio of 1:2.27–1:3.58 has been reported [66, 67].

In Fig. 7, the relative reduction of green house gas emissions of different biofuels compared to a gasoline-fueled car is outlined. It can be easily seen that the reduction varies enormously with the type of feedstock

Biodiesel. Figure 7

Reduction of GHG emissions from different biofuels in relation to fossil gasoline-fueled passenger car [68] *ice* internal combustion engine, *hyb* hybrid

and fuel. Overall a reduction of GHG emissions can be seen, the best values are obtained for biodiesel from sunflower oil and BtL Fischer–Tropsch diesel from wood chips. Bioethanol from corn and sugar beet does not show high reduction, however, bioethanol from sugar cane, which is not included in the figure, has the best values. Also biodiesel from palm oil or used frying oil or animal fat is not outlined but has a very good GHG saving potential.

According to the European Directive on the promotion of the use of energy from renewable sources [61] biofuels should reach at least 35% GHG reduction compared to fossil fuel. With effect from January 1, 2017, the greenhouse gas emission saving from the use of biofuels shall be at least 50% and from January 1, 2018, that greenhouse gas emission saving shall be at least 60% for biofuels produced in installations in which production started on or after January 1, 2017. It has to be mentioned that the data from the European Directive are based on the energy allocation method, whereas the figures presented in Fig. 7 are calculated according to the substitution method, which come closer to a real life cycle assessment.

Biofuels according to the new European Directive shall not be made from raw material obtained from land with high biodiversity value, like primary forest and other wooded land, namely forest and other wooded land of native species, highly biodiverse grassland, wetlands, and continuously forested areas.

Regarding the minimum values for GHG savings within the directive, there are typical and default values for the different biofuels produced from different sources. The default values could be used, if there are no own calculations for a specific type of biofuel, the typical values are mean values from literature data, which are always slightly higher. In Table 5, it can be seen that biodiesel from soybean oil would not meet the minimum value of 35%, so in that case it has to be proved case by case by individual calculation, that the real value are over 35%. The minimum value has to be reached by each feedstock, so blending to reach the limit is not allowed. As the minimum value will be increased up to 50% in 2017 and up to 60% in 2018 only biodiesel from waste cooking oil or animal fat will be above the limit. This would be a high risk for biodiesel from vegetable oils, if there

Biodiesel. Table 5 Typical and default values for reduction of GHG according to the European directive 2009/28/EC [61]

Biodiesel type	Typical value	Default value
Biodiesel rapeseed oil	45%	38%
Biodiesel sunflower	58%	51%
Biodiesel soybean	40%	31%
Biodiesel palm (process not specified)	36%	19%
Biodiesel palm (process with methane capture at oil mill)	62%	56%
Biodiesel waste oil/animal fat	88%	83%

would not be any significant improvement of the whole life cycle assessment. However, within the next years there will be need for further adjustments and adaptations in order to guarantee sustainable biofuel production.

Future Directions

Within the next decades, there will be a constant rising demand for biofuels due to lack of alternatives in the transport sector and the need for lowering the emissions of green house gases. Due to national and international legislation especially so-called second-generation biofuels will be favorized, which are produced from nonfood biomass like lignocellulosic material. For heavy-duty vehicles mainly used for transporting goods diesel fuel is the main energy source. One possibility to produce second-generation biodiesel is gasification of biomass and further synthesis via Fischer–Tropsch reaction (biomass to liquid, BtL). This technology however is not yet commercialized industrially because of complicated and expensive installations. So fatty acid methyl or ethyl esters produced out of fatty acid material will be still the dominant biofuel in the diesel sector in mid-term perspective. However, the kind of feedstock will be more and more focused on nonfood crops like oil from *J. curcas* or microalgae. Also the use of waste material like used cooking oil or animal fats will become more interesting. The traditional sources for production of biodiesel like rapeseed oil, soybean oil, and palm oil will still be dominant, but it is also

clear that this kind of feedstock could never substitute a significant amount of total demand of transport fuel. Theoretically microalgae, which could be grown on nonagricultural areas, could be produced in such amounts to substitute the total demand of fuels; however, a lot of research still has to be carried out in order to lower the total costs of cultivation and processing. Also all the different feedstock have to be evaluated and compared with life cycle assessments and the social impact of production and processing has to be considered carefully. So all in all biofuels will play an important role as alternative fuels in the transport sector as long as transport is based on combustion engines.

Glossary

Biodiversity The variability among living organisms from all sources, including, “inter alia,” terrestrial, marine, and other aquatic ecosystems, and the ecological complexes of which they are part: This includes diversity within species, between species, and of ecosystems (United Nations – Convention on Biological Diversity).

Connectivity Landscape connectivity is the degree to which the landscape facilitates or impedes movement of plants and animals among habitat patches (cf. [70]).

Corridors and stepping stones Corridors are linear strips of habitat through the landscape of which the length, width, and design are depending on the species. Instead of continuous corridors, for some easy-migrating species (e.g., some bird species) also so-called stepping stones could support their dispersal through the city. A stepping stone connection consists of a subsequent series of small patches of habitat positioned between larger habitat structures [24, 25].

Dispersal Process of individuals leaving the place where they are resident (home) and looking for a new place to live. This behavior can occur both within and between habitat patches [33].

Fragmentation Describes the emergence of discontinuities (fragmentation) in an organism’s preferred environment (habitat), causing populations to get isolated from each other, and increased disturbance of remaining habitat. Habitat fragmentation can be caused by geological processes that slowly alter the layout of the physical environment, or by human activity such as land conversion (e.g., natural area that gets “developed” into city area), which can alter the environment much faster and causes extinctions of many species (Wikipedia).

Habitat An ecological or environmental area that is inhabited by a particular species of animal, plant, or other type of organism. For wildlife in cities, this

includes the total area used for foraging (e.g., gardens, parks), reproduction, and nesting (this may include buildings, e.g., for bats and some bird species), resting, hibernating, and migrating.

Habitat network An interconnected configuration of habitat patches and corridors.

Habitat patch A relatively homogeneous area that differs from its surroundings. Patches are the basic unit of the landscape that change and fluctuate, a process called patch dynamics. Patches have a definite shape and spatial configuration, and can be described compositionally by internal variables such as number of trees, number of tree species, height of trees, or other similar measurements [25].

Homogenization Biotic homogenization is the process by which the similarity of a biological variable increases across time and space. In the perspective of this chapter, the term “homogenization” is used to describe the increasing similarity of urban wildlife communities (especially “bird species”) in cities across the globe [44].

Landscape ecology The study of how the spatial structure of landscape elements (= different parts of the landscape) affects organism abundance at the landscape level, as well as the behavior and functioning of the landscape as a whole. This includes studying the influence of pattern, or the internal order of a landscape, on process, or the continuous operation of functions of organisms [71].

Metapopulation A metapopulation consists of a group of spatially separated populations of the same species which interact at some level. A metapopulation is generally considered to consist of several distinct populations together with areas of suitable habitat which are currently unoccupied (Wikipedia).

Urban wildlife This includes all non-domesticated animals, plants, and other organisms that live in city environments.

Definition of the Subject

Worldwide, the diversity of plant and animal life is diminishing at high speed. At the same moment, more and more humans become city dwellers, with both the proportion and absolute number of people living in cities increasing rapidly. An important link

between global biodiversity loss and fast urbanization is the enormous ecological foot print by urban dwellers, the huge demand for natural resources as required by the urban life style. Besides, a generally less well-known impact of the global urbanization of human society is the extinction of wildlife experience. People in cities lack frequent and intense human-nature interactions, as compared to our rural history. This leads to a decreased understanding of and support for plant and animal life. This not only negatively impacts biodiversity conservation efforts; it also restricts the long-term abilities of humans to benefit from nature. By promoting *urban* biodiversity, nature will be enhanced in the direct living and working environment of citizens, enabling humans to reconnect with nature.

This chapter addresses the opportunities to enhance urban biodiversity and its experience by citizens. First we illustrate how the city environment is perceived from a wildlife point of view, which is necessary to recognize opportunities to enhance urban biodiversity. Next, we discuss these opportunities one by one, illustrating with examples how to implement them in practice. We conclude with an exploration of future possibilities to integrate urban biodiversity conservation opportunities in the broader concept of sustainable city planning, design, and management.

Introduction

Why Attention for Urban biodiversity?

The latest global Living Planet Index [79] shows a decline of biodiversity about 30% between 1970 and 2007. This is based on trends in 7,953 populations of 2,544 mammal, bird, reptile, amphibian and fish species. We may therefore conclude that global biodiversity loss is currently happening on an immense scale and rate. This loss of biodiversity not only impacts ecosystem functioning, but also human well-being. The fact is that the world's ecosystems provide a wide range of services (so-called ecosystem services) that are of vital importance for the quality of human life. Degeneration of these services has huge direct or indirect negative consequences for human life: for example, (local) extinction of bees decreases pollination service and consequently food production linked to seed [2].

The urban growth of human society can be considered as one of the main causes of global biodiversity loss. According to the United Nations [73], the level of world urbanization crossed the 50% mark in 2009. In addition, between 2009 and 2050, the world population is expected to increase by 2.3 billion, passing from 6.8 billion to 9.1 billion [72]. At the same time, the population living in urban areas is projected to gain 2.9 billion, passing from 3.4 billion in 2009 to 6.3 billion 2050. Thus, the urban areas of the world are expected to absorb all the population growth expected over the next four decades while at the same time drawing in some of the rural population [73].

The impact of human lifestyle on the natural ecosystem, illustrated by a concept as the ecological footprint, is extremely high for humans living in cities [53]. As example, the city of Vancouver, Canada, requires 180 times more land to generate and process materials than the city actually occupies [52]. Already in the 1970s it was documented that modern cities consume 10–100 times more energy (per unit area) than natural systems [50]. All in all, the urban life style is an important cause of the worldwide decline of ecosystem functioning and biodiversity. It is therefore counterintuitive to think of urban areas as focal areas for biodiversity conservation, however there are several arguments to do so [45]:

1. *Source approach to diminish environmental impact:* As the majority of people is concentrated in urban areas, exploiting conservation efforts in cities (1) will reach many people and (2) any reduction in the huge city's environmental impact will be a positive step toward sustainability.
2. *To reconnect humans with nature:* Most people who live in urban areas are largely disconnected from nature. This means that a worldwide "extinction of (wildlife) experience" is currently taking place. To counteract, the places where people live and work should be designed so as to provide opportunities for meaningful interactions with the natural world. Doing so has the potential not only to engender support for protecting native species, but also to enhance human well-being [48]. Urban wildlife experience has psychological benefits for citizens [26] and may contribute to so-called socio-ecological systems, as such being an important

strategy to enhance the resilience of local citizens (see [23]).

3. *To recognize cities as (potential) biodiversity hotspots:* People, plants, and animals share the same preference for areas naturally rich of resources. Urbanization is occurring in numerous (former) biodiversity hotspots worldwide, and has been identified as a primary cause of declines in many threatened and endangered species [49]. Although urbanization processes often have diminished a large part of the original biodiversity richness, the remnant “green space” (according to its management) usually still contains a certain (potential) value for biodiversity conservation. For example, the UK city of Sheffield inhabits a high number of bird species ($n = 77$), with only three nonnative species [27].

A Different Scope: Approaching the City from a Wildlife Point of View

In natural situations, the appearance and change of landscapes and their attached biodiversity are products of abiotic and biotic processes. Human activities, such as agriculture, modify these relationships. In the urban landscape, the hierarchy of processes is absolutely different: Here, the biodiversity settlement is first depending on human appreciation and management, abiotic and biotic factors play a less important role. So, to better understand how plants and animals may survive in these man-made landscapes, a good understanding of the different actors in the urban environment and the “realities” they perceive is crucial.

Obviously, cities accommodate a range of human actors. Apart from humans as individuals inhabiting in the city (the “residents”), city dwellers employ various activities that makes that they can also be grouped as e.g., students, sportsmen, entrepreneurs, employees, patients, (allotment) gardeners, elderly people, or urban professionals (the latter term referring to those people who professionally deal with city planning, design, and management), etc. Depending on their age, societal status, and individual preferences, citizens may fit in only one or in a whole set of urban actor groups. Moreover, each of these urban actor groups, including residents, has its own favorite part of the city. They also have each their own demands

concerning what the city should deliver: Residents like nice and safe residential neighborhoods; sportsmen and - women like good and sufficient sport accommodations; etc. This makes that city planning and design can be a complex process, as there usually are many urban stakeholders to be involved.

Some of the “actors” in cities are nonhuman, being plants and animals. Most species are considered as real “wildlife” because they survive in the city on their own; others are domesticated and (partly) depend on care by humans (pets and cultivated garden plants). For all of them, cities provide them with different needs, in essence similar as for humans, being “habitats” where they can live, eat, reproduce, move, and communicate with others. However, wildlife generally has specific habitat requirements that are generally different than those of humans. For example, most birds prefer trees and shrub as nesting place above buildings (although there are exceptions as swifts and house sparrows).

To understand what the city is like as wildlife habitat, humans should project themselves in the plants and animals that inhabit city environments. This is because wildlife often evaluate the reality of the city in a different way than people would do. Three different realities of the city can be perceived by human and nonhuman urban actors:

- *Biophysical reality:* The reality of what is physically there: buildings, roads, vegetation, bare soil, open water. Geographers use to describe the physical reality (“land cover”), these days more and more supported by satellite and aerial photo images. Urban actors (both human and wildlife) perceive the biophysical reality as (one of) the realities they have to deal with.
- *Functional reality:* The reality of how the city is actually *used* by different urban actors. In their use of the city, human actors thereby take the biophysical reality (what’s there?), the functional reality (how the city is being used by themselves and others), and the planning and design reality (what is it meant to be?) in consideration. Wildlife only look to the biophysical and functional reality, the latter including the human and wildlife use. Obviously, wildlife does not take the planning and design reality into account, as they are unaware of city plans.

- *Planning and design reality*: This reality has to do with what a specific part of the city officially is designated as, or what it meant to be for. The planning reality is predominantly shaped by urban professionals in planning and design (architects, landscape architects, urban planners, regional and landscape planners etc.), and subsequently assigned in municipal, regional, federal or national plans and documents, and as such taken in consideration by human actors.

Figure 1 presents an example that illustrates the differences between the realities, and why it is important to be aware of the differences among the realities and the way they are perceived by humans and wildlife in the city.

City Environments as Wildlife Habitat

Cities as Landscape

Although most people would only associate rural and natural environments with the term “landscape”, city environments can also be considered as real

landscapes (e.g., [12]). This is because due to their size (usually $>100 \text{ km}^2$) they act on a landscape level, and because of their distinctive land use pattern they sharply contrast from their rural or natural surroundings. From a wildlife point of view the features of the urban landscape determine its habitat suitability and availability.

As the urban landscape largely consists of buildings and paved area, its stony and built-up character makes that they resemble rocky and cliff landscapes. Sky scrapers thereby act as mountain cliffs, whereas the streets between high-rise buildings (e.g., in Manhattan, New York) act as canyons. For species as the Peregrine falcon (*Falco peregrinus*), these high-rise city environments have become a secondary habitat, next to their natural cliff habitat.

Cities also appear to be different in terms of climate, as compared with the often more vegetated surrounding landscapes such as forests, swamps, mountains, or agricultural land. Because of their stone surface (and lack of the evaporation possibilities that vegetation

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 1

The Garden snail *Cornu/Helix aspersum* is a cosmopolitan species, originating from the south of Europe (Mediterranean). Buildings and surrounding green (*biophysical reality*) are considered by the snail as part of its urban habitat (*functional reality*), meanwhile humans designate these housing areas as living areas for themselves (*planning and design reality*). The coexistence of humans and these snails in residential areas leads to positive and negative interactions: the garden snail is seen as a pest for garden flowers, but also inspires people through its appearance and behavior, and acts as food for e.g., birds (which are preferred urban wildlife by residents). Photo: Robbert Snep

has), cities warm up faster, effectively retain the heat, and throw it out during the night. In addition, exhaust gases (traffic and industry) and the heating of buildings add up to an increased temperature, especially during nights. The main reason for the nighttime warming, however, is that buildings prevent surface heat from radiating into the relatively cold night sky. As a result, city night temperatures surpass the average regional temperature with several degrees. During days there is also a, yet smaller, difference in temperature. This “being warmer than the rural surroundings” phenomenon is called the UHI (*urban heat island*) effect (e.g., [69]). The UHI effect causes health problems for humans during the summer (as it contributes to extreme heat, which causes high mortality rates), but also affects wildlife in different ways. For example, in temperate climates (sub)tropical plant and animal species are more likely to survive in city environments than in the natural or rural surroundings of the city. In Northwest Europe, plant species as Common Fig (*Ficus carica*) and Olive (*Olea europaea*) from the much warmer Mediterranean region can survive in sheltered spots within cities, but would die in the rural surroundings of these cities during winters. The same process is observed on small Mediterranean ferns in France [18] showing that cities therefore present an interesting preview on how global warming may support the invasion of thermophilic species into currently colder regions.

There are more features that distinguish urban landscapes from natural and rural environments. One of them is air quality. Because of traffic and industrial gasses, the quality of city air is often worse than in the rural surroundings. The air pollution directly limits the habitat suitability of cities for e.g., most lichen species but also impacts the survival rates of urban plants and animals in general [6].

Cities are places with an excess of noise. Car traffic is a main cause of city noise, thereby making it difficult for some animal species to communicate. For example, for territorial birds it is hard to make themselves heard through the traffic noise and as such to defend their territories [54]. Recent studies have shown that bird species may adapt to the noisy city environment. Urban Coal tits (*Parus major*) sing at a higher pitch than their rural congeners, to compensate for the city background noise [61]. From other birds it is known that urban

individuals start to sing earlier in the morning than usual for these species, to avoid the noise of the city’s rush hour.

Cities are constructed in a variety of places, neglecting whether the physical conditions of the original soil may support the construction of buildings. Some cities are developed in (coastal) wetland regions or in peat soil areas, locations that are not well-equipped for construction buildings. To compensate for this, urban developers make their development sites “construction ready” by removing the original upper soil layer and adding construction-supportive sand layers. In most cities this urban development process has been happening for ages, making that urban soils are highly heterogeneous, with many different soil compositions within a small area. In addition, pedogenesis (the formation of soils) is disturbed by the actual urban land use. As large parts of the city consists of buildings and roads, these parts are sealed and thus isolated from normal interaction with rain and surface water, plant life, sun heat, etc. Also, because of the weight of buildings and heavy car traffic, the soils are compressed, decreasing their permeability for water and soil organisms. On top of this, a portion of the pollution and eutrophication coming from industry and traffic will find its way to the urban soil. As an example, urban soils often appeared to contain much higher levels of heavy metals such as lead than its rural surroundings [19]. All in all, urban soils are quite different than rural and natural soils, more contaminated and eutrophicated, as soil profiles less developed (because of a disturbed pedogenesis), spatially more heterogeneous and – with all this – thereby in general impacting the habitat quality of cities for plant and animal life in a negative way. An exception would be that, because “to be” urban development sites are usually covered with sand, these young sandy soils provide a – often temporary – habitat for plant and animal species from early successional vegetation [64]. These pioneer habitats enrich the species composition of the city’s biodiversity (Fig. 2).

The cycle of water (from clouds, precipitation, surface or groundwater back to clouds via evaporation) is essential for life on earth. On a landscape level, there are huge variations in the amount of water in each part of the cycle, as the cycle of water is taking place on a continental or even global level. In the vegetated

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 2

The Natterjack toad (*Bufo calamita*) is a pioneer species of early successional habitats, including urban fringes.

Left: tadpoles (black) of this toad species in a small temporary water body at a development location. *Right:* the male toad calling during mate season (Photo: Robbert Snep)

parts of the world, being the areas where most human activities occur, human land use has disturbed the water cycle process. In agricultural areas, the surface and ground water flows are highly manipulated to optimize crop yield. In urban areas, this manipulation of water has taken a much more far-reaching level. Surface water is largely canalized, with stony and steep embankments. Sewer systems catch most of the water that precipitates on buildings and streets. In cities with naturally high groundwater levels (like former wetlands), groundwater is sometimes drained or leveled in another way. The evaporation process in city areas is, due to the lack of vegetation, rather poor. In addition, urban water is contaminated by (former) industrial and household waste and by traffic, especially in cities where sewer systems do not function optimally. All in all, water is strongly manipulated in city environments. As water is a vital element for plant and animal life, the deviant quantity and quality of urban water restricts the habitat quality and availability for wildlife in cities.

Cities as Mosaic of Biotores

Although city landscapes are quite different than rural and natural landscapes, they are all but homogeneous.

City landscapes are in fact composed of a wide variety of urban land use types, ranging from residential areas, business districts, shopping malls, and (rail)road structures to urban parks, sport field complexes, allotment gardens, and cemeteries. Within each of these land use types, the actual land cover or soil occupation may also vary quite largely. The spatial heterogeneity is what makes the city that there is not such thing as “the urban biotope” (Fig. 3). Cities are mosaics of biotopes.

For long, ecologists have undervalued city environments in terms of species richness and composition. Most ecologists thought (and many of them still think) that cities would not accommodate a diversity of plant and animal life worth to study. A pioneer in the scientific field of urban ecology, Prof. Herbert Sükopp, provided the counterintuitive insight that cities are rich of species and numerous interesting ecological patterns and processes can be found here. In the 1960s, in the middle of the Cold War between the West and the Soviet Union, he was positioned at a university in West Berlin (Germany). By that time, West Berlin was governed by the West, but the surrounding area controlled by the Soviet Union. Normally, academic ecologists would leave the city and do their field work in rural and natural areas. This was not possible in the

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 3

Illustration of spatial distribution and portion of vegetation in different urban land use types: sporting fields (*right top*), residential areas (*right bottom*), infrastructure (*left*) and industrial sites (*center*). IKONOS satellite image (Photo: Robbert Snep)

case of West Berlin. Herbert Sükopp therefore decided to conduct his ecological field research within the urban area of West Berlin, a unique approach. By mapping the plant communities and biotopes of residential areas, shunting yards, and derelict industrial areas in the city in a systematic way, he discovered that urban environments have a much higher flora and plant community richness than expected. From further studies conducted in German cities, it was later also demonstrated that especially the transition zone from city to rural surroundings is species rich, and that the flora richness of cities can even be higher than the actual surrounding rural land [37]. This latter is due to two facts: (1) the heterogeneity and biotope richness of urban areas and (2) the low flora richness of the intensively managed agricultural regions in which many (German) cities are located. Modern operational management methods of farms focus on optimal yield for agricultural products, and include reshaping of the landscape (stripping off hedgerows, ponds etc.) for this purpose. Many of

the species of traditional agricultural landscapes have disappeared in the modern agricultural “deserts” due to lack of habitat; some of them find a new habitat in the small-scaled structure of the city edge. As an example, Sálek et al. [55] described a case in which the Grey Partridge (*Perdix perdix*) has colonized derelict parcels in business districts and industrial land located at the city edge.

Urban biotopes can be classified in different ways. Based upon the three realities (biophysical, functional and planning and design reality, see section “A Different Scope: Approaching the City from a Wildlife Point of View”), each classification having its pros and cons. With the *biophysical or land cover* approach, good insights in the abiotic conditions are provided, enabling ecologists where potential habitat for wildlife could be found. For this purpose aerial or satellite images supply with basic information on where vegetation and other habitat characteristics are located (using e.g., infrared sensing techniques), but additional field work is required to detail the land cover of urban

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 4

Bird monitoring in urban environments is not only conducted in backyards and urban parks, but also at industrial sites. At this photo ecologist Martin Melchers is observing urban gulls nesting at the roof of storage tanks in the Port of Amsterdam (NL) (Photo: Robbert Snep)

areas. With the *functional* approach, the actual use of the urban area by wildlife and humans is mapped. Wildlife can be monitored with a variety of techniques, of which bird counting techniques (e.g., by mapping territories) are probably most well known (Fig. 4). With these monitoring techniques, a good overview of the current habitat value of the urban area for wildlife species can be acquired. With additional inventories on the human use (recreation, traffic) of the urban area, possible causes for differences between apparently similar plots can be demonstrated. In Madrid (Spain) a study to the foraging behavior of Blackbirds (*Turdus merula*) in several urban parks showed that in parks frequently visited by people, the Blackbird behavior and density was different then in similar parks with a lower frequency of visitors [21]. Blackbirds in the more crowded parks spent more time being vigilant and moving away from people and less time searching for food (decreasing food intake). The number of pedestrians was positively correlated with Blackbird distance to pathways and negatively correlated with distance to protective cover. The number of active birds decreased with increase in the number of pedestrians during the day. Blackbird density was negatively related to the number of visitors per park. This study confirmed that human disturbance negatively affects

Blackbird feeding strategies in urban parks, ultimately modifying spatial and temporal patterns of habitat selection and abundance [21]. This study also shows that land cover and land use destination alone (in this case “urban park”) can be insufficient to determine the habitat value of urban biotopes for wildlife. The actual use of the biotope by others (humans, dogs) appears to have a – though rather invisible – impact. To implement urban ecological knowledge into the design, management, and use of the city (see “planning and design reality”), one should be able to link an urban biotope classification to the design and management jargon and concepts of the city’s public space, residential areas, business districts, etc. As there is much variety in habitat quality and quantity within each of the official urban land use types (as assigned in zoning plans), the official land use legend of the city is often not well-equipped for mapping ecological knowledge, so translation between these two different classifications can be difficult.

Fragmentation and Connectivity of (Urban) Habitat

From the 1970s on, ecologists have linked the spatially explicit availability and connectivity of habitat at the landscape scale with the abundance of species at the

local scale. Ecological theories as the island biogeography [42] and the metapopulation theory [39, 51] explain how local plant and animal populations are depending of surrounding populations for their long-term persistence. The first publications about these theories mark the start of the scientific discipline of “landscape ecology.”

The island biogeography originates from comparative studies on species richness of islands and mainland, thereby illustrating that islands with a larger size and a smaller distance to the mainland are more species rich than small islands that are located far from the mainland. The size of the island thereby is a good predictor of the probability of local population extinction. The smaller the island, the generally less habitat; the smaller the island population, the higher vulnerability for a disaster to impact the whole island population, the higher the extinction rate of the island population. After local extinction, the island may be inhabited again via colonizing individuals deriving from the mainland. The distance to the mainland thereby acts as a good predictor for the colonization probability: the smaller the distance, the larger the chance that the island will be re-colonized. The island biogeography theory can also be applied in situations where there is a very large “source population” (the mainland) and smaller local populations, all located in a larger area of non-habitat.

In the past, habitat used to be much more abundant and interconnected than in current landscapes. In today’s human-dominated landscapes habitat is not only reduced in size and quality, but also fragmented by infrastructure and urban development. Here, the island biogeography with its mainland that acts as source area is not applicable, as there often is no enormous mainland habitat. The metapopulation theory is better equipped for these fragmented landscapes.

The metapopulation theory departs from the idea that in fragmented landscapes interconnected local populations may together make up a so-called metapopulation. The long-term persistence of such a metapopulation is achieved by the network setup: (1) local population extinction should be balanced with new colonization from neighboring local populations and (2) the total number of all individuals within the metapopulation should be sufficient. With an extra large local population (a so-called

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 5

Illustration of how networks of local populations (so-called metapopulations) of a ground-dwelling species are distributed in and around a city (pink). Road (orange) and water (blue) infrastructure act as barriers and makes that there are different metapopulations (that instead of one large network). As a result, some metapopulations have sufficient size to overcome environmental fluctuations, and are viable (green), others are too small and are nonviable (red) (Photo: Robbert Snep)

key-population), this total number can be lower than in case all local populations within the metapopulation are small. As the interlinkage between local populations is crucial for the mutual exchange, the habitat pattern at landscape scale determines whether local populations will together function as a metapopulation (Fig. 5).

Several landscape parameters determine the probability that species may survive in the landscape:

- Habitat availability (the amount of habitat available for the species)
- Habitat quality (determines the carrying capacity per area of habitat)

- Habitat connectivity (extent to which habitat patches are mutually connected)
- Individual habitat patch size (determines whether there is a habitat patch in the landscape with sufficient space for a key population)
- Landscape permeability (extent to which the landscape pattern support the migration of species through the landscape, especially the size and character of the portion of nonhabitat is important in this case)
- Barriers (landscape structures that prevent the movement of species through the landscape (e.g., highways for ground-dwelling animals))

Also, some species-specific parameters determine how well the species would be equipped to survive in the landscape:

- Dispersal capacity (extent to which a species is able to migrate through the landscape, e.g., overcome barriers.)
- Dispersal distance (distance that individuals of a species are able to travel to colonize new habitat)
- Home-range size (the size of the area that an animal individual uses during everyday's activities)
- Disturbance sensitivity (level at which a species will be so much disturbed by traffic, recreation, noise, light, etc. in its habitat that this will impact its survival probability)
- Local population size (minimum amount of individuals required to function as local population)
- Key population size (minimum amount of individuals required to function as key population (and thus as an source for neighboring populations) [74])
- MVP size (minimum amount of individuals within the metapopulation necessary for a minimum viable population [59]; for metapopulations with a key population the minimum is lower than without a key population, [74]).

Each landscape is unique, each species is unique; however there are some general rules about how to deal with landscape planning and design, as seen from the viewpoint of biodiversity conservation:

1. Conserve (or re-develop) sufficient habitat area for conservation target species. "Sufficient" should meet habitat criteria for *viable* plant or animal populations [67].

2. Use the SLOSS (Single Large patch Or Several Small patches) principle while targeting (to be) habitat patches for conservation [1, 60]. This is as habitat networks should have sufficient size for a (meta) population size and sufficient connectivity (to support colonization of the patches).
3. To meet criteria for habitat connectivity, make sure that the habitat in the area is optimally interconnected, so species can migrate from one habitat patch to another [58]. In landscape and conservation planning, so-called ecological corridors are often assigned to support plant and animal dispersal [24]. These corridors are linear strips of habitat through the landscape of which the length, width, and design are depending on the species. Instead of continuous corridors, for some easy-migrating species (e.g., some bird species) also so-called stepping stones could support their dispersal through the city. A stepping stone connection consists of a subsequent series of small patches of habitat positioned between larger habitat structures.

Urban environments are highly fragmented landscapes, in which habitat availability and connectivity is generally insufficient to support the population viability norms of many species. So the application of the previous concept is not so easy. It appears today, after some urban studies on species dispersal and landscape availability to conserve populations, that complementary consideration has to be suggested in these highly fragmented urban landscapes. For example, the SLOSS rule is generally not possible and it seems interesting to promote also small green spaces and diverse kinds of green structures in dense city environments. The goal here is not to construct new large patches of biodiversity when it is not possible, but to permit, at least, both the dispersal of a maximum of species with "stepping stones" and to increase the interface between nature and citizens. After all, increasing the street plantation (street trees, road verges) in an ecological way would promote for several species the dispersal opportunities in towns: from park to park, and between areas of private gardens and business areas.

Another process that is generally forgotten is the impact of the city on the capacity of species dispersion at regional level. Under climatic change, wildlife

modifies their biogeographical area of distribution, moving to the north [32]. This adds a justification to the need of a good capacity of continuity in landscape at all the scales, including the urban areas. The town becoming megalopolis with continuous building land use acts as barriers to the species movement and especially to the dispersion to new area (to the north) for all the species that move with difficulty. Given transparency to the town, e.g., permitting the species movement is also a challenge of a sustainable city.

Urban Wildlife Species and Communities

On Eating and Being Eaten

The food resource and/or its quality are an important factor of the settlement of animal in town. The availability of grass for first consumers, insects or gastropods for first predators and small vertebrates for second predators are fundamental both to explain the presence of species in a habitat and to explain the stability of the biodiversity through the quality of the food chain. Obviously the urban areas do not present all the availability of food for each step of the food chain and some kinds of animals are favored. For example, the omnivorous and detritivorous animals, small (snails, flies...) as well as large (gulls, corvids, rats...) ones, are capable to use the rubbish dumps and all wastage from human activities. These species can become very numerous and create several problems of cohabitation (e.g., [10]). Other species take advantage of the feeding behavior of inhabitant that is important in private as well as public spaces. This typical urban source explains the success of pigeons [30] but also of some exotic species such as parakeets introduced in numerous towns [68]. However, the use of refuse is commonly reported for other species living in urbanized areas, for example, tits [14], blackbirds [57], gulls [7], or mammals such as raccoons [43] or foxes [56].

In general, urban areas appear clearly poor in food resources for specialist species. Wetlands are scarce, so water birds and aquatic fauna are also scares. The absence of old trees that permit settlement (shelter, food) of numerous insects and birds also explain the absence of several communities of animals. However, the town presents more and more vegetation and welcomes more animals today than some decades before.

Insectivorous birds seems to decrease in numerous European town in 1970s [28], but today these birds appear to be more numerous with the reduction of car pollution and pesticide use. In the same time, the recent reduction of some garbage sources in numerous countries has also limited the proliferation of some problematic animals (rats, gulls, ...).

For some generalist birds breeding in towns, a behavioral flexibility exists through diet plasticity, for example the Herring Gull [7], while for other generalists, such as the starling, it is less clear. Starlings can modify their diet composition in winter [20], but its diet variability in towns during the breeding period seems to be limited [46]. However, successful generalists compensate for feeding resource difficulties (poor quality of food, accessibility) linked to urbanization, and their behavioral flexibility allows to achieve similar breeding performances in rural and urban areas.

One of the characteristics of urban green spaces is the presence of a majority of exotic plants and trees. The consequence could be directly observed at the level of the community composition (e.g., more "coniferous" birds in town than in rural areas – [15]) as well as at the level of feeding behavior. For example, the bees give a more rich honey in town linked to the great diversity of exotic flowers. The quality of some urban food (richer, more fat) involves also some differences in individual morphology, and obesities can be observed in urban animals [35].

Wild predators are present in towns: foxes or stone martens are more common in suburbs but also sometimes in downtown [28]. Birds of prey such as falcons or sparrow hawks are today present in numerous European cities and some have adapted to the urban constraints changing their food items. The kestrel that eats small mammals in rural areas hunts particularly sparrows in towns. But the most important predator in town remains the domestic cat that eats numerous small birds (robins, house sparrows, ...), small mammals (shrew, vole, ...), and fragile lizards [22, 78].

Reproduction

In the same way than for food availability, the possibility to find nesting places explains the settlement or not of the species in the urban areas. For example, the study of breeding birds in town shows clearly the absence of

birds of open habitats, especially ground-nesting species such as larks [15], that need high grass and quiet places. Lancaster and Rees [38] found that cavity nesters were at an advantage in cities. However holes (in building or in trees) seem very dependent of the history of the building or of the park. The number of cavities in building appeared rapidly decreasing with the new architecture and the protection of all walls. In addition, linked to the hard urban disturbances, birds nest the higher possible and the installation of nest boxes (that are generally not sufficiently high) do not resolve always the problem of the lack of cavity. However, the management of parts of public parks in a more ecological way (especially increasing shrub plantation) favors the availability of the nesting places for numerous passerines. In the same time these sites become progressively more acceptable for a small fauna of soil, litter, grass, and shrub.

The reproduction success is highly variable according to the species. Urbanization profoundly affects the reproductive parameters of birds [9]. Mennechez and Clergeau [47] observed in starling that (1) although the rate at which parents feed their nestlings was higher in urban areas than in rural ones, the amount of food delivered to nestlings by parents in town was weak and (2) the body mass of nestlings reared in the urban sector was significantly lower. This supports the idea that urban nestlings received insufficient food loads or food of low quality (refuse food). Urban environment imposes severe constraints in terms of nutritional “conditions.” So some generalist birds such as starling can have bad reproduction in town when generalist species such as the kestrel can have good urban breeding performance [36]. It seems difficult to generalize a relationship between habitat generalist and specialist, without integrating the capacity of adaptation of the different species.

Territorial Behavior

The behavior of wildlife in town is not well studied and today only some mammals have been seriously analyzed. For example, it is well known that cats change their social organization and their territorial behavior in town. In natural and in rural areas, wild cats or

domestic cats each have a stable home range with only some spatial overlaps; the organization avoids all possibility of temporal contact. In town, the social organization is absolutely changed: Cats leave in group with one or two dominant males. The impact of punctual and abundant source of food (by human feeders) explains this structure [40].

The fox has been well studied and comparison between rural and urban are conducted in several countries (e.g., [31]). All the studies give the same results: The territory of urban foxes is smaller in town and changes regularly of place. The higher mobility of urban foxes is linked to the high mortality that involves change of individual and permanent reorganization of territories, but also to the shelter availability. In town the majority of fox holes do not exist and animals sleep during the day just in flower clumps, within pipeline, under bridge, etc.

Alien and Invasive Species

Numerous exotic animals and plants have settled into new geographical regions after voluntary or involuntary releases by humans. Although only 1% of alien plants have established populations and spread (Williamson 1996), this percentage can reach 15–50% for vertebrates [34]. When these alien populations increase in number, they often exert negative pressures on the native ecosystem, especially in terms of predation or competition with native species [75]. However, in numerous cases, the mechanisms underlying their success and the potential impacts of these aliens are not sufficiently well documented. The urban areas are the first source of introduced species [16] for plants with horticulture and garden plantation, and for animals with trade of pets. This process becomes an important point of biodiversity management also in town with the goal of urban corridors permitting the dispersion from and to the town (see after).

Consequently, a change in the work of landscape gardeners is awaited in order to limit the use of exotic species known as invasive in new garden and park management. This is especially important for site adjacent to rural and natural zones.

For animals too, the trade need to be examined but also the behavior of citizen that releases all kind of

exotic pets. One recurrent human behavior that seems to facilitate the establishment of exotic species in temperate regions and often in town is the supplemental provisioning of food. The provisioning behavior is observed for numerous exotic mammals (e.g., Coypu *Myocastor coypus*, Siberian chipmunk *Tamias Sibericus*, Grey squirrel *Sciurus carolinensis*), and birds (e.g., Mute swan *Cygnus olor*, Rock dove *Columba livia*, Rose-ringed Parakeet *Psittacula krameri*) and it could be one of the keys to the success of these species. Limiting the supplemental feeding of alien species could be an element of management for some invasive species and needs to be evaluated [13].

Urban Survival Strategies

Blair [4] working on birds and butterflies defined different kind of species according to their ability to colonize and settle in the town. He recognizes species that avoid the urban areas (the “avoiders” that are never present in this habitat) from species that exploit the town (the “exploiters”). These exploiters are generally “adapters” that modify their behavior to exploit better the town. Urban environment seems to impose so many constraints on birds (e.g., landscape fragmentation, isolation of habitat patches, noise, pollution, type and availability of food resources, human activities, vegetation quality in habitat patches. . .) that only species that have a (pre-) adapted way of life are able to tolerate them. Croci et al. [15] suggested that the urbanization filters bird species on the basis of their traits. That biological filter effect of urbanization seems to be a key determinant explaining which passerines can be found in town, urban adapters, and which cannot, urban avoiders. Studying bird avifauna at local and regional levels in France, Croci et al. [15] found 45 urban adapters that were mainly species that preferred forest (15 species) or meadow (14 species) habitats rather than open landscapes or aquatic habitats. The habitat availability in cities is a key determinant of the biological filter that urban constraints play on bird species from natural areas. Global abundance of species is not the main factor explaining their presence in cities. Indeed, urban adapters and avoiders were not associated with any of the modalities of the number of species pairs. Geographic distributions of urban

adapters were especially wide and involved more diverse biogeographic areas than urban avoiders generally from temperate climates.

Most species with high nests are associated with tree availability and, therefore, forest habitats, whereas nesting at low or medium heights is often correlated to shrubby, aquatic, or open and appeared as gregarious species. Being with congeners landscapes, omnivorous species were at an advantage in town, whereas granivorous species were at a disadvantage. Eating a variety of food items permits an exploitation of new resources linked to the town, such as garbage. Croci et al. [15] observed also that at the contrary of urban avoiders, urban adapters did not especially present a plumage coloration dimorphism and that urban avoiders were associated with more than two clutches per year and less wingspan when compared to urban adapters. Urban adapters seemed to have larger life expectancy than urban avoiders and were more sedentary that may enhance opportunities to learn from others birds experience, for example, for food location or predation avoidance, and thus, be at advantages in new environments such urbanized areas. Urban adapters also molt once a year whereas urban avoiders molt two times. All these traits lead us to believe that during the breeding season, urban avoiders have not much resources as urban adapters to allocate for adaptation to urban areas.

Homogenization

Biotic homogenization is the process by which the similarity of a biological variable increases across time and space. According to the nature of the variable, homogenization is qualified of taxonomic when there is an increase of the similarity of species between biotopes, functional when there is an increase of the similarity of biological traits (e.g., biological characteristics), and genetics when there is an increase of the similarity of the gene pool.

Each eco-region presents its own pool of species; however, in town the species are often the same [5]. McKinney [44] suggests that the urbanization modifies the community of species, decreasing the specialist species (increasing the generalists) and increasing alien species. Consequently, the similarity between

community increases with urbanization and gives biotic homogenization. In USA the part of alien exotic species is high and can explain a large part of the homogenization; in Europe, alien species are not so numerous [11] and the homogenization is linked to the increase of similar generalists. The explanations could be obtained in the similarity of the urban variables through the world (light, buildings, laws, climate, etc.).

Opportunities to Connect City Actors with Urban Nature

City Planning

The overall shape of cities has a large impact on the extent to which wildlife can colonize city environments, and to which humans can experience these plants and animals. On the one hand, there are the circular-shaped cities, of which the urban fringe – the zone where city and rural nature may interact – is minimal. Besides, the distance from the rural habitats to the city center of such cities is large, and as a result wildlife has to overcome many barriers to colonize inner-city areas. On the other hand there are starfish-shaped cities, where in between built-up areas there are so-called green wedges that may penetrate all the way to the city center. These green wedges often are remnants of former natural stream habitats or other, linear-shaped natural structures that were conserved during the urbanization process. In these starfish-shaped cities, wildlife can much easier migrate through the city environment. Moreover, for citizens the proximity of green in these green-wedge cities is much higher than in circular-shaped cities.

At a next level, it is the design of the “green within the urban area” that has great influence on the abilities of citizens to interact with nature. Within the domain of green space planning, the city’s internal major green structures are planned. The challenge is to find a balance between the portions and configuration of built-up area and those of urban green. From an estate development point of view, one could aim for a maximum portion of built-up area. Although this seems economically favorable at first sight, from a quality-of-life perspective a minimum amount of urban green is demanded to make that people like to live and work in such cities. Urban planners and

landscape architects, therefore, plan for green structures as public gardens and parks in between new residential and business areas to provide recreational opportunities and support the visual qualities of the built-up areas.

From the wildlife point of view, the way in which green structures are planned is crucial. Not only the amount and size of green structures, but also their mutual cohesion and their connectivity with the rural hinterland determines the habitat suitability of city environments. If urban planners aim to optimize human-nature interactions in the city, they should consider that continuous green structures are best to support wildlife movements, and thus enable plants and animals to inhabit the areas where people live and work. Thereby, wildlife will not discriminate between public or private green (as long as the habitat quality is fine), so connecting public parks with private garden complexes would favor wildlife [29].

Another aspect to take into account is that different plant and animal species may use different parts of the urban green as their habitat. Forest species (like woodpeckers) perceive large open green areas (e.g., grassland or swamps) as nonhabitat and rely on forest and trees structures for their habitat and dispersal opportunities. Other species may prefer swamp vegetation of river banks (e.g., dragon flies), or the flower-rich vegetation of extensive grassland (e.g., butterflies). To support a rich diversity of plant and animal species in the city environment, interconnecting similar types of biotope (forest with forest etc.) is necessary.

To some extent, peri-urban areas may determine the richness of urban nature. Peri-urban areas are the rural areas that are located adjacent to the city. Snep et al. [65] illustrated for butterflies that such peri-urban areas could act as source areas to strengthen nature in the inner-city. With sufficient habitat (in quality and quantity), local butterfly populations may thrive. A surplus of these butterflies may disperse from the peri-urban areas into the city using the urban green structures as dispersal corridors. City planners could take advantage of the natural value of the peri-urban area by tuning the type and structure of the urban green with the peri-urban nature. By doing so, they may optimize the opportunities for peri-urban wildlife to colonize the city.

Different Opportunities for Different Parts of the City

The public green and water structure in cities can be considered as the basis for the city's ecological functioning, due to its size and connectivity. Public green areas with predominantly lawn and solitary trees have little habitat value for the urban wildlife and its experience by citizens. If the urban green is however designed and managed in a more ecological way, a whole array of plant and animal species can be accommodated. Especially the abundance of brush and shrub vegetation containing native plant species will contribute significantly to the habitat quality of the urban green. This is, as these vegetation layers act as reproduction habitat for birds, butterflies, dragon flies etc. Also, the banks of streams and other urban water bodies have a good potential for wildlife, if not "engineered" with concrete sheet piling.

For most citizens, urban parks and water bodies are the places where "urban nature" can be experienced. Although these public areas can make up an important contribution to the city's wildlife habitat, there are

other, often private, areas that have good capacities to enhance the experience of urban nature by citizens. These areas are residential neighborhoods, school environments, and business districts.

Residential Neighborhoods A good way to (re)connect humans with nature is to enable citizens to experience nature in their own backyards. Many people like birdlife around their houses (especially songbirds), a conclusion that can be derived from the large portion of residential gardens with bird feeders and nesting boxes [17]. Abundant and diverse birdlife, however, is depending on more factors than only these specific bird features. To attract birds to residential areas, there should be enough habitat (being "urban green") in and around houses so birds have opportunities to eat, rest, reproduce, and gather. A high portion of urban green, as well as sufficient variety in plant species and vegetation structure, do not only enhance bird life, but also other animal groups as mammals (e.g., hedgehogs, bats) and insects (butterflies, (bumble)bees) (Fig. 6). Plants provide different habitat functions as food

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 6

Urban green in the ecological housing area The Cherry Garden (NL), designed and maintained such that both biodiversity conservation as biodiversity experience is supported. The nectar plants and shrub provide habitat for butterflies, (bumble) bees, and song birds, the whole setting with the residential area is inviting for citizens to really experience the wildlife (Photo: Robbert Snep)

source (e.g., host and nectar plants for butterflies) and as reproduction or resting place (e.g., shrub and trees for bird nests). Native garden plants generally provide more habitat value for biodiversity than exotic garden plants, as the local animal life has coevolved with native plant species. Some exotic plant species are exceptions, like the cosmopolitan Butterfly bush (*Buddleja davidii*) that is a nectar source for butterflies in many parts of the world.

Incorporating small water bodies (garden ponds) in the gardens and neighborhood green structures adds extra habitat value to residential areas. Water habitats offer habitat for species with an entirely aquatic way of life (like fish and water plants), and also provide places to drink and forage for many terrestrial animal species. Additionally, they offer reproduction and nursery habitats for species with a partial aquatic way of life (e.g., amphibians, dragon flies).

On average, private gardens are too small to accommodate enough habitat, for example, a bird's territory. Animals therefore move between gardens to visit different resources. The urban design of the residential area as well as the vicinity of larger urban green areas have a great impact on the extent to which resources in a particular garden will be used by animals. If gardens are clustered, and fences between the individual gardens are permeable for wildlife, animal abundance will be more likely than in cases where gardens are walled and isolated from other green. Also, the presence of larger urban green areas in the vicinity of residential areas increase wildlife abundance, especially as there good opportunities for wildlife to exchange between urban green areas and residential neighborhood.

Finally, if wildlife is present in residential areas this does not automatically mean that citizens are aware of their presence, and as such are able to fully experience the diversity and phenomena of plant and animal life. On average, citizens often have low abilities to detect the presence of wildlife, as more and more citizens lack a history of growing up with wildlife [48]. There are two ways to increase wildlife experience opportunities:

1. To improve the visibility of wildlife for citizens, create habitat resources for wildlife in such way that wildlife will expose itself (to some extent) to

citizens. Well-known examples are nesting boxes and feeders for birds, other examples are bee trap nests, nectar hot spots for butterflies (e.g., group of butterfly bush), and garden ponds. A more sophisticated way is installing webcams in bird and bat boxes, or infrared cameras for nocturnal wildlife.

2. To improve the wildlife detection ability of citizens. Educate citizens in detecting wildlife, using binoculars (birds) and netting (insects, aquatic life) and tracking (ground-dwelling mammals) techniques. Often, (local) conservation groups are best equipped to stimulate and educate people on wildlife monitoring, using citizen science for conservation purposes.

School Environments Richard Louv [41] wrote a well-known and inspiring book, entitled "Last Child in the Woods," addressing the rapidly decreasing experience of (urban) youth with nature. This book gives a plea for (re)connecting youth with plant and animal life. School areas are perfect places to do so, as children will spend a large part of their early years in these environments. School yards can be designed and managed such that wildlife experience is optimized. Replacing a part of the school yard tiles by urban green that has good habitat value for butterflies, birds, (bumble)bees will stimulate children to explore nature. By actually involving children in the realization and management of this "school nature," they will perceive it as "their own" nature (Fig. 7).

Not only at school yards but also at other places in the direct vicinity of schools there are opportunities to let children experience wildlife. In the Dutch city of Eindhoven, more than 20 primary and secondary schools participate in the "school pond project," a municipal project in which ponds and nearby schools are managed and monitored by youth, supervised by local wildlife experts and teachers. During classes the children visit the ponds, making sure they are well informed about the developments of the local nature. If necessary, additional conservation measures such as habitat improvement are executed to enhance populations of local plants and animals. Linking the outdoor school nature with the actual school lessons on environment and biology offer opportunities to

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 7

Greening project at a primary school, together with the children. Plants with added value for biodiversity are planted (*left*), attracting small wildlife that can be experienced (*right*) (Photo: Soontjens Stadsnatuur)

provide more background information about the local wildlife, and support children to understand the diversity of life and the working of the ecosystem.

Business Districts “Business districts” can be further classified as high-quality business sites, mixed business sites, logistic areas, heavy industrial areas, and seaport areas. Other names for these areas are business sites, business parks, industrial sites, industrial districts, or industrial estates. Opportunities for business sites to provide ecosystem services are now gradually being recognized. For example, recent studies have focused on how flat roofs, a typical feature of business site buildings, can be used (designed as green roofs) to reduce urban air pollution [80] or road traffic noise. Regarding biodiversity conservation at business sites, some initiatives are already under way in current practice. The US Wildlife Habitat Council (WHC) encourages corporations to voluntarily manage lands for wildlife and biodiversity protection, and certifies companies that substantially contribute to biodiversity conservation on their corporate lands [76]. Cardskadden and Lober [8] studied the benefits to corporations of participating in the WHC programme in terms of its influence on relationships with key corporate stakeholders including employees, host communities, environmental groups, and regulators. They report that at 164 sites, 95% of respondents indicated that wildlife

habitat programs had led to improved employee morale; 72% indicated improved relationships with environmental groups; 60% noted a positive effect on community relations; and 49% of respondents reported improved relations with regulators. These benefits were in addition to the annual cost savings reported by 50% of the programs. Besides, relationships with the community, government, and environmental groups led to better wildlife programs due to increased expertise.

In another example, the UK British Trust for Ornithology (BTO) awards companies that take specific measures to conserve bird diversity on their lands. The Business Bird Challenge began in 1994 and is a partnership between businesses, the BTO, and local communities which encourages biodiversity on business and industrial sites. Sites range from working quarries, power stations, and oil refineries to research establishments, company headquarters, and restored nature reserves. The aim is to maximize the potential of business sites for birds and other wildlife whatever the business site size.

In the Netherlands, Dutch Landscape Management promotes the integration of landscape elements and species conservation measures into business site development. They aim to raise awareness among municipalities and the business community, but also among project developers and designers,

Biodiversity in Cities, Reconnecting Humans with Nature. Figure 8

Overview of how the greening of business sites with vegetation attractive for wildlife may improve both the business site as its urban and rural surroundings. The quality of life in adjacent residential areas can be enhanced by common wildlife originating from the business site [65]. The quality of work can be improved as the green enhances the aesthetic and recreation perception in the business environment [64]. The biodiversity in natural habitats near the business site can be enhanced as the business site may offer specific habitat for endangered butterflies and other species [66]

regarding opportunities and advantages that “green” business sites offer. They thereby focus on fitting business sites into their surrounding landscape, enhancing the ecological significance of business sites and increasing the accessibility of the sites for recreation purposes.

Business sites, often located at the city’s edge, can offer habitats for rare species (e.g., pioneer butterflies and amphibians), which mainly occur in the surrounding rural landscape, and for common species that also occur in the city [63, 65, 66] (Fig. 8). This implies that if biodiversity conservation is incorporated in business site planning, design, and management, the effectiveness of investments in conservation measures will increase if the target species and type and amount of habitat are attuned with the regional context of ecological networks.

Biodiversity conservation at business sites can be shaped in different ways, each with its own (socio) economic and environmental characteristics. There are different options for biodiversity conservation at business sites: green roofs and walls, a more ecological management of the conventional business green, temporary early successional vegetation on vacant parcels, and the design of ecological corridors and stepping stones throughout the business site. Results from a stakeholder survey on this topic suggest that implementing measures to enhance biodiversity may be acceptable only if combined with other green

functions (predominantly “recreation” and “health and well-being”) and if suited to the functional appearance of the business site environment (“external appearance” and “tidiness”) [64] (Fig. 9).

Future Directions: Integrating Wildlife Conservation in Sustainable City Planning and Design

Future directions in research, education, and practice on integrating wildlife conservation in sustainable city planning and design may focus on:

1. Climate-proof city green with ecological value
According to Pauleit et al. (see chapter “► [Green Infrastructure and Climate Change](#)”) urban green may support the resilience of cities toward climate change, as vegetation is able to cool (evaporation, shade) city environments and storage storm water (pervious soil). This demand for additional, climate-proof, urban green opens an opportunity to enhance the ecological quality of the city, if executed in the right way. As example, green roofs have excellent capacities to deal with heat and storm water (see chapters “► [Green Roofs, Ecological Functions](#)” and “► [Green Roof Infrastructures in Urban Areas](#)”), however the *Sedum* monoculture roof type – that is currently applied at large scale – has less ecological value than green roof types with more diversity in plant species (preferably,

native), soil type, and depth and other characteristics. A challenge for the future therefore is to design and manage the urban green meant for climate change mitigation purposes in an ecological way.

2. Urban agriculture with ecological value
Allotment gardens in city environments are an ancient phenomenon, subject to societal trends and thereby increasing and decreasing in popularity over time. A whole new global trend is the concept

of urban agriculture, beyond the traditional allotment garden. Urban farms produce food for the city, within the city itself. A well-known and quite extreme example are the urban farms at roof tops in New York City. Urban farms appeal to the current demand for “home-grown food.”

Urban agriculture provides habitat opportunities for urban wildlife and wildlife experience, if the agricultural practices are based upon biological principles (e.g., no pesticides). Urban farmers as well as visitors of these farms will thereby experience how natural processes like pollination are essential for growing food. Though this used to be basic knowledge among people for ages, citizens often have lost this knowledge. Urban farms are therefore excellent places to teach citizens about vital ecosystem services such as pollination and biological control. A future challenge is to integrate the urban agriculture concept in the city planning and design, as such that this phenomenon contributes to the basic understanding of citizens about the natural world they live in.

3. Urban energy and commodity production with ecological value

With successive energy and commodity crises worldwide, urban regions start to explore possibilities to produce their own energy and commodities, thereby decreasing their dependence from energy and commodity producers outside their region. There are several ways to produce energy, using different techniques.

One way to generate electricity or commodity comes from biomass. Although urban regions in general have a low production of biomass (e.g., prunings of tree and shrub vegetation from urban green management), this method may enhance the citizens' awareness about energy (“burning”) and commodity (“biorefining”) production, and also provides an added value to the city green. If in the near future urban biomass targets are set, this may lead to more shrubs and trees in the city, meaning more habitat for wildlife. The biomass topic represents future benefits that urban green may provide and that are currently not taken into account by urban planners and landscape architects in city development (see also chapter ► [Urban Forest Function, Design and Management](#)).

Another way of producing energy in cities is by solar panels at roof tops. These solar energy systems work most efficiently if the outside temperature is not too high. At roof tops covered with bitumen, the temperature will increase too much for optimal functional of the solar panels. At green roofs the direct surrounding of the solar panels is cooled by the vegetation (evaporation) and thus there is more efficiency.

Snep and Opdam [62] and Beatley [3] have addressed the opportunities to integrate natural values in urban planning and design quite extensively, like in Fig. 10. These publications focus on the “nature” aspect of urban green. There is however a much larger, global trend of “green cities”, in which “nature” is not mentioned explicitly. The term “green” here refers to “sustainable” (“green” being a modern alternative) or “vegetated” (“green cities” uses urban vegetation for its societal benefits). A challenge may be to connect these two worlds, to enable planners, (landscape) architects, project developers, and others to integrate wildlife conservation in the planning and design of sustainable cities. Future directions as mentioned above (climate-proof, urban agriculture, urban energy) can be seen as starting points to come to green, ecological cities with contain mutual benefits (both sustainable and natural).

Glossary

Bioethanol Ethanol produced by fermentation of sugars from plant materials, for example, sugar, starch, or cellulose.

Enzymatic hydrolysis A reaction where enzymes are used to catalyze splitting of molecules to smaller units by addition of water. Here, enzymatic hydrolysis refers to splitting of cellulose to glucose.

Ethanol fermentation The use of microorganism, in most cases yeast, for conversion of sugars to ethanol.

Flow-sheet design The use of computer programs for design and/or rating of complex production facilities, usually based on a conceptual drawing (flow sheet) of the process.

Lignocellulosic material A common name for plant biomass containing cellulose, hemicellulose, and lignin (e.g., hardwood, softwood, straw, bagasse).

Pentose fermentation Fermentation of sugars containing five carbon atoms, like xylose and arabinose, which are the main constituents in the hemicellulose fraction in agricultural residues and hardwoods.

Pretreatment Lignocellulosic material is by nature very recalcitrant to degradation. By pretreating the material, the structure is made more accessible for degradation by enzymes or microorganisms.

Process integration To design the unit operations involved in a process while considering the interaction between the units and to combine them in an optimal way. For instance, efficient use of heat and power is made possible by utilization of, for example, waste heat internally (in the plant), or externally (in a nearby plant), which can diminish requirement for expensive equipment, such as steam boilers.

Second-generation bioethanol Ethanol produced – in a sustainable way – from lignocellulosic materials (e.g., forest or agricultural materials).

Definition of the Subject

Bioethanol can be produced by fermentation of sugar present in the carbohydrate fractions (i.e., hemicelluloses and cellulose) available in all lignocellulosic materials. These could be agricultural residues (e.g., wheat straw, corn stover, sugarcane bagasse), forest residues (e.g., branches, tops, saw dust, thinning material), and energy crops (e.g., salix, hemp, Miscanthus, switchgrass).

To make ethanol from cellulosic materials is very similar to making ethanol from starch. First, the carbohydrates, hemicelluloses and cellulose, have to be hydrolyzed to monomer sugars and after that fermented to ethanol by a microorganism (e.g., yeast). There are, however, two major differences compared with starch ethanol:

- The structure of the lignocellulosic material is more difficult to break down due to stronger bonds between the sugar molecules in cellulose and the interaction between cellulose, hemicellulose, and lignin.
- While starch and cellulose are made up entirely of glucose, hemicelluloses comprise a variety of sugars, both pentoses (i.e., sugars with five carbons) and hexoses, which makes it difficult to find a single microorganism that can ferment all of these sugars.

This makes production of bioethanol from lignocellulosic materials much more complex than starch-based ethanol production. A third factor that differs is the presence of lignin, which protects the carbohydrates from degradation and makes enzymatic hydrolysis of the carbohydrates more difficult. However, having a lignin coproduct is also a possibility to improve the process economy as it can either be used as a valuable coproduct for chemical production or used for heat and power production as it has a higher heating value than the original biomass.

Introduction

Ethanol is currently the dominating renewable biofuel within the transport sector. It has been introduced on a large scale in Brazil, the USA, and some European countries and the production is expected to continue increasing during the years to come. The global production of ethanol in 2009 reached 73.9 billion liters [1]. Ethanol can easily be integrated in the existing land transportation infrastructure as a blend with gasoline, up to 20% ethanol, or as a neat alcohol in dedicated engines, taking advantage of the higher octane number and higher heat of vaporization. It is also an excellent fuel for future advanced flexi-fuel hybrid vehicles.

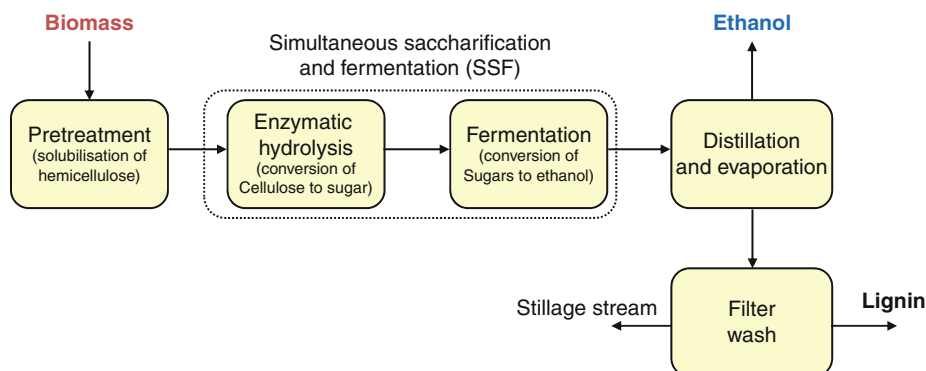

Ethanol can be produced through fermentation from a variety of sugar-containing crops such as

sugar beet, sugarcane, sweet sorghum, and fruits; starch-containing crops such as corn, wheat, and potatoes; and so-called lignocellulosic material such as agricultural wastes, wood, and municipal waste. Ethanol produced in this way is sometimes referred to as bioethanol.

The production of ethanol from sugar and starch is a well-established technology, which has been used for many years mainly for production of alcoholic beverages, but also for fuel ethanol in the last few decades. Currently, ethanol for the fuel market is produced from cane sugar (Brazil) or corn starch (USA) at more or less competitive prices. However, this raw material base, which also has to be used for human needs and animal feed, will not be sufficient to meet the increasing demand for fuel ethanol, and the reduction of greenhouse gases resulting from use of sugar or starch-based ethanol is not as high as desirable [2].

It is, therefore, a general opinion that future expansion has to be based on bioethanol from lignocellulosic material, which is usually called second-generation bioethanol (2G). These raw materials are sufficiently abundant and also available worldwide. They generate very low net greenhouse gas emissions and thus helping to reduce environmental impacts. However, processes for the production of ethanol from lignocellulosic materials are much more complex and not yet fully developed although several pilot plants and some demo plants have been in operation during the last couple of years. The main by-product of the processes is a solid residue consisting mainly of lignin, which can be used as a fuel, where the market is basically unlimited, or to make products of higher value in order to improve the process economy.

A process for bioethanol from lignocellulosic material consists of the following main steps: Hydrolysis of the carbohydrates (i.e., cellulose and hemicelluloses), fermentation of all sugars to ethanol, separation and upgrading of the ethanol to water-free ethanol, wastewater treatment, and combustion of the solid residue for production of steam and electricity required for the process (Fig. 1). The various process steps can be performed in many different ways and also the overall process configuration can vary. Furthermore, the ethanol process can be integrated with other types of industrial processes. A selection of important possibilities is described below.

Bioethanol from Celluloses. Figure 1

Simplified process for production of ethanol from lignocellulosic materials

Bioethanol from Celluloses. Figure 2

Cellulose chain

Within the explanations given below, the principles for ethanol production from cellulosic materials, recent developments in the bioconversion processes, and future challenges are outlined. First, characteristics of biomass in general are presented together with typical material compositions for various lignocellulosic feedstock, followed by a summary of different process options for hydrolysis of biomass. This chapter focuses on one option – the enzymatic route – which is covered in more detail with some important methods for pretreatment of biomass. In a process, hydrolysis is followed by fermentation of sugars, which is an area with intense research. Full-scale plants are considered next and the necessity of process intensification and process integration are discussed in depth with a number of examples.

Basics

The composition of lignocellulosic materials differs from one species to another. However, the main

constituents are of the same type: about 50–60% carbohydrates in the form of cellulose and hemicellulose, 20–35% lignin, and some other valuable components like extractives, fatty acids, and ash.

- Cellulose* is the major component in the cell wall of plant cells consisting of linear chains of linked glucose units and it is the most abundant macromolecule on earth. The degree of polymerization (i.e., the number of glucose units) vary between 2,000 and 20,000. Every glucose unit is rotated 180° with respect to its neighbors and linked by β -1,4 glycosidic linkages, making the repeating unit the disaccharide cellobiose (Fig. 2). The linear chains associate strongly via intra- and interchain hydrogen bonding, which causes aggregation into so-called microfibrils with a largely crystalline structure combined with some amorphous regions. These microfibrils are highly stable and resistant to chemical attack, which makes cellulose insoluble in most common solvents, including water, and also very resistant to (enzymatic) hydrolysis.

- *Hemicellulose* consists of short, highly branched chains of heterogeneous polysaccharide sugars, comprising both five-carbon sugars, called pentoses (usually D-xylose and L-arabinose) and six-carbon sugars, called hexoses (D-galactose, D-glucose, and D-mannose) [3]. The branches also contain other groups (e.g., acetyl groups and glucuronic acid). The degree of polymerization is much lower than for cellulose, around 200. Hemicellulose is more hydrophilic and easier to hydrolyze than cellulose. The main carbohydrate in hemicelluloses from agricultural crops and hardwoods is xylose, while mannose is dominating in softwood (Fig. 3).
- *Lignin* is the major non-carbohydrate component in lignocellulosic materials comprising a highly complex, three-dimensional polyphenolic compound. It is closely attached to the cellulose and the hemicellulose and is responsible for the remarkable strength of plants, especially trees. The primary building units of softwood lignin are mainly guaiacyl, with minor amounts of syringyl and

p-hydroxy-phenylpropane units, while hardwood contains more syringyl units (Fig. 4).

Cellulose can be hydrolyzed to glucose according to the following chemical formula:

that is, theoretically 1 kg of cellulose results in 1.111 kg of glucose.

Bioethanol from Celluloses. Figure 4

The guaiacyl (left), syringyl (middle), and *p*-hydroxyphenyl (right) units in softwood lignin

Bioethanol from Celluloses. Figure 3

Example of hemicellulose chains. (a): o-acetyl-galactoglucomannan; (b): arabinogalactan-4-O-methylglucuronoxylan

This is also valid for hydrolysis of the anhydrosugars in the hexose fraction in hemicelluloses, while the hydrolysis of the pentose fraction would be:

that is, theoretically 1 kg of xylan (or arabinan) may yield 1.136 kg of xylose (or arabinose).

The sugars can then be fermented to ethanol using some microorganism, like yeast or bacteria, which theoretically can result in 0.51 kg of ethanol and 0.49 kg of CO₂ from 1 kg of sugar (either hexose or pentose) according to:

Table 1 shows typical compositions of some selected lignocellulosic materials. The composition may differ depending on where the biomass grows and at what time of the year it is harvested. For three of the materials, the standard deviation is given based on at least five different samples to show the extent of variations. The hemicellulose in agricultural crops and hardwood is primarily composed of pentose sugars, while softwood hemicellulose has a large fraction of the hexose mannan. This is reflected in the amount of ethanol that can theoretically be produced from 1 t of dry matter for the various biomasses according to the formulas given above (Table 1). It is quite clear that pentose

fermentation is not so important for efficient utilization of softwood while it may constitute up to 40% of the potential ethanol production from agricultural crops like corn stover and wheat straw or from grass like switchgrass.

For spruce up to 50% of the energy can theoretically be obtained in the ethanol (if all the sugars are converted to ethanol) and another 35% is obtained in the coproduct lignin. In a real process, less than this theoretical yield will be obtained because of losses in the conversion and due to the needs for energy, heat, and power in the process.

In a longer perspective, lignin may be used for production of chemicals. Lignin is a very complex molecule, which contains numerous aromatic compounds of which some have interesting properties. In contrast to the coproduct from starch-based ethanol production (DDGS, which is used as animal feed), there is no real limitation for the use of the lignin-rich residue as a fuel. About the same ethanol yield could be expected from different crops, although agricultural residues in general contain less lignin; thus, the energy contribution from the lignin part will be lower.

Besides the carbohydrates and lignin, most lignocellulosic materials also contain other compounds like extractives and ash. The agricultural crops may also contain some residual fractions of starch, proteins, and pectin. The amounts of these compounds vary a lot between different types of lignocellulosic materials

Bioethanol from Celluloses. Table 1 Composition of various lignocellulosic materials in percentage dry basis (values in brackets are standard deviations from several studies)

	Glucan	Mannan	Galactan	Xylan	Arabinan	Lignin	Ethanol C6	Ethanol C5	Reference

and are also affected by the geographical site of cultivation, the soil, and the season. These compounds are usually not discussed very much in research on ethanol production but must of course be considered in full-scale processes. They may both be an asset, in terms of coproduct value, and a problem due to influence on the biological conversion steps.

Process Options

There are several options for a lignocellulose-to-ethanol process but, regardless of which is chosen, the following challenges must be addressed [12]:

1. Efficient depolymerization of cellulose and hemicellulose to soluble sugars.
2. Efficient fermentation of a mixed-sugar hydrolysate containing six-carbon (hexoses) and five-carbon (pentoses) sugars as well as fermentation inhibitory compounds.
3. Advanced process integration to minimize process energy demand.

4. Integration with external processes for cost-efficient use of lignin and residual organic matter.

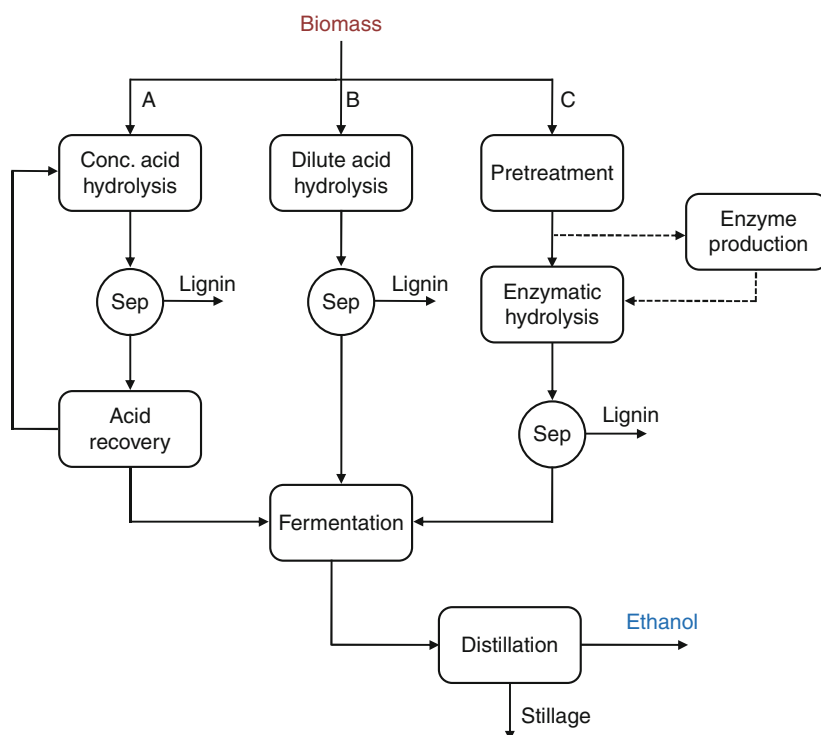

The first step in the conversion of biomass to ethanol is size reduction and hydrolysis of the carbohydrates. This can in principle be performed in three ways (Fig. 5):

- (a) By use of concentrated acid hydrolysis
- (b) By dilute-acid hydrolysis
- (c) By enzymatic hydrolysis

Either way, the target is to access the cellulose and hemicellulose to generate individual sugar monomers for the fermentation process. In the following section, a summary of various methods is presented.

Concentrated Acid Hydrolysis

Concentrated acids (e.g., sulfuric, hydrochloric, hydrofluoric, and nitric acid) can be used to dissolve native cellulose at rather low temperatures. If the mixture is diluted with water and heated, the cellulose is

Bioethanol from Celluloses. Figure 5

Different routes for hydrolysis of lignocellulosic materials

hydrolyzed to monomer sugar. This has been known since the 1880s [13] and has been used in several full-scale processes during the twentieth century. For example, in Germany, several full-scale plants for hydrolysis of wood using concentrated hydrochloric acid (40% HCl) were operated during World War II. Several plants based on concentrated sulfuric acid were commercialized in the middle of the twentieth century in the former Soviet Union and in Japan [14]. However, these processes have only been run under times of national crisis and the products (e.g., chemicals, fuel, and feed) were not competitive on international markets.

The process results in rather high yields, but the large amount of acid used creates several problems such as corrosion and pollution. Furthermore, the dilution of the acid in the second hydrolysis step requires high amounts of energy for acid recovery. Nevertheless, the process using concentrated sulfuric acid has gained renewed interest due to the inventions of new methods to separate the acid from the sugar solution, based on ion exchange.

Dilute-Acid Hydrolysis

Dilute-acid hydrolysis of biomass is the oldest technology for conversion of cellulosic materials into sugars. The first commercial plant for production of ethanol from wood based on acid hydrolysis of sawdust, and using diluted sulfuric acid, was built already at the end of the nineteenth century. Since then, several plants have been operated in the USA, Japan, Germany, and the former Soviet Union [15]. There are still some plants operating in Russia. Most of the old plants were run with one-stage hydrolysis using some kind of percolation, where liquid is flushed through the reactor to remove the sugars formed. The main drawback was a moderate yield of sugars and also very dilute sugar solutions, which required a considerable input of energy in the distillation step for recovery of ethanol.

After 1973, several research programs were started around the world to improve the yield and increase the sugar concentration of this process. In the first step, hemicellulose is hydrolyzed under milder conditions (170–190°C), while in the second step the cellulose is hydrolyzed under more severe conditions (200–230°C). However, the high temperatures required for

hydrolysis of the cellulose also result in sugar decomposition, which not only decreases the yield but also produces compounds that inhibit the microorganisms in the fermentation step. Also for a two-step acid hydrolysis, the overall sugar yield is usually lower than 60% [16].

Enzymatic Hydrolysis

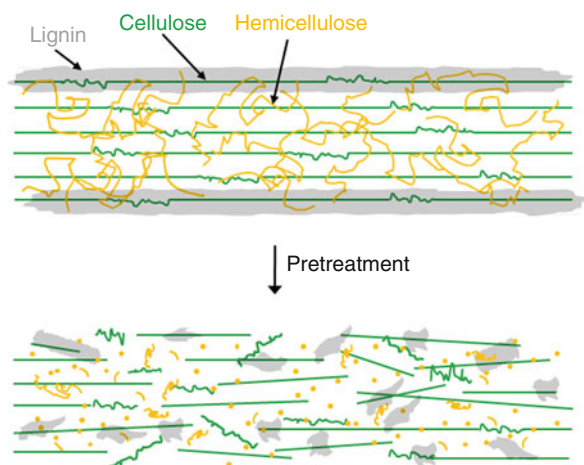

One of the most promising process alternatives for production of sugar for fermentation from woody materials is the enzymatic process [17–19] because of its potential for high yields. Figure 5 provides a schematic view of the process. The enzymatic hydrolysis process comprises the following main steps: pretreatment of biomass, enzymatic hydrolysis, including enzyme production, fermentation of all sugars, ethanol upgrading, wastewater treatment, and heat and power production.

However, the hydrolysis of lignocellulose using enzymes can be hampered by the very low reaction rate. Lignocellulosic materials are by nature very recalcitrant and not very many microorganisms can degrade them in a fast and efficient way. The main reason is the requirement of a whole array of enzymes, each having more or less specific activity on a certain type of polymeric fragment, such as cellulases, xylanases, mannanases, and lignases.

It is, therefore, of vital importance to pretreat the material to alleviate the enzymatic attack on the structure. The complexity and interconnectivity of the polymers constituting lignocellulose materials makes it necessary to open up and/or partially hydrolyze the structure (Fig. 6). After pretreatment and enzymatic hydrolysis, the process steps are very similar to what is used in concentrated or dilute-acid hydrolysis processes (Fig. 5).

Enzymatic Hydrolysis Route

In general, enzymatic hydrolysis can be considered as more favorable to use than acid hydrolysis because of the milder conditions and higher potential yields of sugars. It does, however, require the pretreatment step, which can constitute a substantial fraction of the overall cost. Therefore, the enzymatic hydrolysis route is discussed below in more detail; however, the parts after pretreatment and enzymatic hydrolysis are to

Bioethanol from Celluloses. Figure 6
Schematic view of the effect of pretreatment

a large extent valid also for the other two process alternatives (i.e., concentrated and dilute-acid hydrolysis).

The pretreatment step is perhaps the single most crucial step as it has a large impact on all the other steps in the process (e.g., enzymatic hydrolysis, fermentation, downstream processing, and wastewater handling in terms of digestibility of the cellulose, fermentation toxicity, stirring power, energy demand in the downstream processes, and wastewater treatment demands).

Pretreatment Methods

Pretreatment, to be effective, should have a number of features [20]. It has to:

- Result in high recovery of all carbohydrates.
- Result in high digestibility of the cellulose in the subsequent enzymatic hydrolysis.
- Produce no or very limited amounts of sugar and lignin-degradation products [21]. The pretreatment liquid should be possible to ferment without detoxification.
- Result in high solids concentration as well as high concentration of liberated sugars in the liquid fraction.
- Require a low energy demand or be performed in a way so that the energy can be reused in other process steps as secondary heat.
- Require low capital and operational cost.

During the last 2 decades, a number of alternatives have been proposed for pretreatment of various substrates. This can be achieved in various ways, using either physical (e.g., milling, grinding, or irradiation), or chemical (e.g., alkali, dilute acid, oxidizing agents, or organic solvents) methods, or (something in between) physicochemical (e.g., steam pretreatment/ autohydrolysis, hydrothermolysis, or wet-oxidation) methods. This classification is rather vague since in some cases it is difficult to put a label on the chosen pretreatment type [21–26]. Some methods are more efficient than others when it comes to yield and recovery of the fractions. Also, some methods are better suited for hardwood or agricultural residues than for pretreatment of softwood, probably because of the different lignin structures in softwood as compared with that in hardwood or agricultural substrates. Below, a selection of important pretreatment methods is summarized.

Physical Methods Chipping, milling, and grinding are methods that aim at reducing particle size and thus increase the surface area exposed to enzymatic attack. The biomass is turned to a fine powder of some microns in size. To some extent decrystallization occurs, which also improves the hydrolysis rate. However, in order to achieve a high digestibility in the enzymatic hydrolysis step very small particles are required, which makes high power consumption unavoidable. Actually, it can be even higher than the theoretical energy content that is available in the biomass [27]. An interesting option could be physical treatment in an extruder combined with heating and addition of chemicals in which case the power requirements can be smaller [28].

Chemical Methods The most common chemical method is to use dilute-acid pretreatment, in which the material is impregnated by soaking (or by spraying) using a dilute strong acid. By heating the wetted material to temperatures in a range of about 140–200°C for a period of a few minutes to an hour, partial hydrolysis occurs resulting in monomeric sugars from the hemicellulose part of the substrate. Typically, sulfuric acid at concentrations less than 4% by weight has been added. The frequent use of H_2SO_4 is due to it being rather inexpensive and efficient. A drawback is the generation

of toxic compounds, if the pretreatment is too harsh, that may be detrimental to the fermenting organism [29–31]. Also, the sulfur may pose a problem if not taken care of properly. The residual lignin-rich fraction can be used for heat generation, but if the sulfur content is too high, it can only be used with careful desulfurization of the effluents. Too high sulfur content in the final ethanol can cause malfunctioning of the fuel-injection nozzles in some engines.

Pretreatment using alkaline conditions are commonly performed at lower temperatures and pressure than is acid pretreatment. When the material is soaked in an alkaline (e.g., hydroxides of sodium, potassium or ammonium), pore swelling results. As a consequence, the internal surface area increases, which makes the carbohydrates more accessible for the enzymes. Besides the area increase, breaking of the lignin–carbohydrate bonds takes place, which also allows for the enzymes to attack the cellulose and hemicellulose chains. Alkaline pretreatment has been shown to be more efficient for agricultural residues and herbaceous crops than for woody materials, as the former type of substrates contain less lignin. To reach similar results using woody materials, the cooking conditions must be much more severe, similar to the Kraft process for pulping.

Lime pretreatment is an alkaline method, which is useful when agricultural or hardwood residues are involved [32, 33]. Due to its relatively low cost, it has become an interesting alternative; also since it can be recovered as solid CaCO_3 when reacted with CO_2 . The calcium carbonate can then be recovered and converted to lime again using a kiln. A disadvantage using calcium-containing salts is the risk for precipitations of, for instance, calcium oxalate, which is a well-known problem in the pulp industry. When process streams containing calcium salts are recirculated in the pulp plant, precipitation often takes place on heat-exchanger surfaces causing scaling.

Organic solvents such as methanol, ethanol, acetone, glycols, or phenol, with small amounts of an inorganic acid catalyst (e.g., HCl or H_2SO_4), comprise foundation for the organosolv method [34]. This option makes use of that lignin dissolves in the organic phase, where it can be recovered using various technologies. It is essential to recover the solvent both for economic and for environmental reasons, but also because the solvent itself may be inhibitory in the

enzymatic hydrolysis and the fermentation steps. When ethanol is used as solvent the recovery is facilitated as this is part of the ethanol production plant.

Physicochemical Methods This category involves methods that combine a physical and a chemical effect (e.g., steam pretreatment with addition of a catalyst, hydrothermolysis, wet oxidation, and ammonia fiber explosion (AFEX)).

Steam pretreatment (sometimes called steam explosion) is commonly used for pretreatment of lignocellulosic materials. It is, in essence, a chemical method very similar to dilute-acid hydrolysis, but usually performed at higher dry-matter contents than is dilute-acid hydrolysis. The typical temperature range is between 160°C and 240°C , with a treatment time of 1–20 min, after which the pressure is rapidly released (“exploded”) and the material transported to a flash-off vessel. It is well suited for most materials, also for softwood. In this case, a small amount of acid catalyst is added to improve hemicellulose hydrolysis; however, when treating agricultural residues or most hardwood species, the inherent acetic acid content is enough to initialize hemicellulose hydrolysis, so-called autohydrolysis. In this case, the final pH is usually around 3–4, while it is set to 2 or less when mineral acids are added. The steam pretreatment method has been tested in pilot- and demo scale.

Hydrothermolysis is similar to steam pretreatment but is performed using more water and usually at slightly lower temperatures and lower dry-matter content. The result of hydrothermolysis is a liquid containing solubilized material, of which much is in its oligo- or polymeric form [35, 36]. This is usually not a problem if the enzymes added during the subsequent hydrolysis are selected to break down the fragments to monomers. For example, autohydrolysis of straw in larger scale has been demonstrated [37]. A variation of hydrothermolysis is the wet-oxidation procedure [38], where air or oxygen is added. This method is suited for materials having low lignin content as the yield has been shown to decrease with increasing lignin content. A drawback is that the lignin is oxidized causing loss of valuable material.

Ammonia fiber explosion (AFEX) is an alkaline method, which operates at elevated pressures, similar to steam pretreatment. However, in the AFEX method,

instead of water, liquid ammonia is added and the substrate is treated for 10–60 min at around 100°C or less [39, 40]. The resulting material contains very much of the carbohydrates in their polymeric forms. If the material is to be fermented, hydrolysis must be performed. However, the material has interesting properties in terms of water-holding capacity and gel formation ability, which can lead to new biodegradable polymer materials (e.g., barrier films and capsules controlled release of drugs). Like other alkaline methods, AFEX performs best on agricultural waste [41, 42], while its efficiency toward wood is lower, probably because of the higher lignin content. The ammonia must be recycled in the process to make it feasible, from economic and environmental aspects.

Biological Methods Biological pretreatment can be performed using microorganisms or individual enzymes to degrade the biomass to polymers [43]. The actual degradation is usually performed using white-rot fungi or brown-rot fungi, which breaks down the lignin or the cellulose and the hemicellulose part, respectively. The method as such has not been attracting too much attention, mainly because some of material is lost in the breakdown process, but also since biological degradation is a slow process and, therefore, would require large treatment units. It would be possible to use the fungi as a first step, while the raw material is stored in piles prior to the main pretreatment step.

Ionic Liquids A rather new approach is to use ionic liquids [44] to fractionate the polymers of lignocellulosic materials. Ionic liquids (IL) are salts, typically consisting of a large organic cation (e.g., 1-butyl-3-methylimidazolium and a small inorganic anion moiety). They exist as liquids at room temperature and are chemically and thermally stable. They act by disrupting the bonds between cellulose, hemicellulose, and lignin thus dissolving the molecules, while forming very little degradation products. So far, it has been demonstrated using pure crystalline cellulose, but some work using straw has also been rather successful.

Before ionic liquids can be used commercially, a number of questions must be answered. It is still not clear how they influence fermenting organisms, although initial tests do not indicate any major problems. However, it is necessary to establish efficient

methods to recover the dissolved macromolecules from the ionic liquid, or, put in other words: how can one recycle the ionic liquids? Currently, the cost for ionic liquids is very high, which makes them less suited for use in production of bulk chemicals, such as ethanol. If, however, value-added chemicals (from hemicellulose or lignin) can be produced in conjunction with ethanol production, and efficient means to recycle the ionic liquids are found, they constitute a very interesting option.

Evaluation Having an array of different pretreatment methods to choose from makes it necessary to have tools for evaluation of the optimal process in terms of economic and operational feasibility. Not only must the pretreatment result in a well-treated substrate, but also the yields of the fractions have to be high. More severe conditions during pretreatment will cause greater degradation of hemicellulose sugars [45–47]. It is also necessary to consider the by-products formed and the impact they may have on the enzymatic hydrolysis and the fermentation steps. It is presently difficult to say that one method is very much better compared to another option without taking into account, for example, the type of raw material that will be used in the process or what by-products can be expected. Also, it is of importance for the economics of the process to consider utilization of the energy content in lignin for internal heating purposes or for the production of lignin pellets for off-site markets.

Several pretreatment methods (e.g., dilute-acid hydrolysis, SO₂-catalyzed steam pretreatment, controlled pH, AFEX, ARP (ammonia recycled percolation), and lime pretreatment) have been compared using the same batch of raw material and exactly the same procedure and conditions for assessment of the pretreated material. This investigation has been carried out for two different batches of corn stover [48] and for poplar wood [7]. The assessment was performed by determining the recovery of glucose and xylose both as monomeric and oligomeric sugars in the liquid after pretreatment and in the liquid after enzymatic hydrolysis of washed solid material (from pretreatment). The enzymatic hydrolysis was performed using solid material at a concentration of 1% glucan (which is a low concentration) and an enzyme dosage of 15 FPU/g glucan of the untreated material. Table 2 summarizes

Bioethanol from Celluloses. Table 2 Summary of studies on corn stover. Yield of sugars^a, in percentage of theoretical available in the raw material, after pretreatment and after pretreatment + enzymatic hydrolysis [48]

Method	Catalyst	Time and temperature	Pretreatment		Pretreatment + enzymatic hydrolysis	
			Xylose	Glucose	Xylose	Glucose
Dilute-acid hydrolysis	H ₂ SO ₄ 0.49%	20 min, 160°C	85.1 (82.8)	6.3	93.6 (91.2)	91.7

^aBased on monomer and oligomer sugars obtained in the hydrolysate after pretreatment and in the enzymatic hydrolysis of pretreated material. Numbers in brackets are for monomer sugars only, when reported

the results for the second batch of corn stover, which are very similar to those for the first batch. The total yield of sugars obtained with the different pretreatment methods was more or less the same, around 90% or more. The main difference is that the low pH methods, like acid hydrolysis and SO₂-catalyzed steam pretreatment, result mainly in monomeric xylose, while the high pH methods (like AFEX) result in a large amount of oligomeric xylose, which requires

also a whole range of hemicellulases in the enzymatic hydrolysis.

Table 3 shows the sugar yields from the poplar-wood study. The yield varies more for poplar than for corn stover. It is higher, especially regarding glucose, for the low pH methods with a glucose yield close to theoretical compared with the high pH methods with glucose yield as low as 50%. Also for poplar, the high pH methods result in more oligomeric xylose, with the

exception of lime. It should also be noticed that for poplar much more severe conditions, like a higher temperature, had to be used (Table 3) compared with the requirements for corn stover.

While many pretreatment methods have been investigated for agricultural waste and hardwood, the number of feasible pretreatment methods investigated for softwood is smaller. It appears that acid hydrolysis and steam pretreatment with acid catalyst are the most appropriate methods [20] to give high sugar yields from softwoods, which are much more recalcitrant than the other lignocellulosic materials. Acid hydrolysis and steam pretreatment with acid catalyst seem to be the methods that can be used for all types of raw materials and these are also the methods that have been most extensively used in pilot and demo plants. However, the drawbacks are the high equipment cost and the formation of inhibitors formed during pretreatment.

In most assessments of pretreated materials, a mixture of cellulases is used in the enzymatic hydrolysis step. Steam pretreatment of corn stover, with and without addition of SO₂, was assessed by enzymatic hydrolysis using ordinary cellulases supplemented with xylanases [49]. The additions of small amounts of xylanases had a major impact on the xylose yield and, surprisingly, even more on the glucose yield (Table 4).

The improvement of sugar yield in the enzymatic hydrolysis of corn stover by addition of xylanase was more pronounced for pretreatment methods that removed less xylose (e.g., AFEX) [50]. However, also for SO₂-catalyzed pretreatment, the increases in

glucose and xylose yields in the enzymatic hydrolysis were about 15% and 34%, respectively. This was also shown for poplar wood [51]. This shows the importance of not using standard methods when assessing pretreatment, but to actually optimize the combination of pretreatment and enzymatic hydrolysis, and preferably also fermentation.

It is important, however, to keep in mind that the assessments described above are not performed under realistic process conditions as the substrate concentration in the enzymatic hydrolysis was very low and the influence of possible inhibitors present in the pretreated slurry was avoided. For a correct evaluation, the fully integrated process must be considered as the various pretreatment methods result in different types of materials. Hemicellulose sugars can be obtained either in the liquid as monomer or oligomer sugars, or in the solid material to various extents; lignin can be either in the liquid or remain in the solid; the composition and amount/concentration of possible inhibitory compounds also vary. This will affect how the enzymatic hydrolysis should be performed (e.g., with or without hemicellulases), how the lignin is recovered, and also the use of the lignin coproduct. This means that all process steps have to be optimized taking into account the special features of the pretreated material, and then comparing the production cost for the various alternatives.

Enzymatic Hydrolysis

Enzymatic hydrolysis of lignocellulosic materials requires a multitude of enzymes, which have activity

Bioethanol from Celluloses. Table 4 Overall sugar yields as percentage of theoretical based on content in raw material after enzymatic hydrolysis of steam-pretreated corn stover (with and without impregnation with SO₂ [48])

Pretreatment conditions	Enzymatic hydrolysis using only cellulases ^a		Enzymatic hydrolysis using cellulases ^a with addition of xylanases ^b	
	Glucose	Xylose	Glucose	Xylose
170°C, 9 min + SO ₂	62.2	67	70.7	70.6
190°C, 5 min + SO ₂	83.2	70.5	96	73.9
190°C, 5 min, no catalyst	69.3	74.6	93.8	85.3

Total amount of protein equal in all enzymatic hydrolysis

toward a variety of molecular groups. For example, to hydrolyze cellulose, at least three different types of enzymes must be present: endoglucanases, which disrupt amorphous areas of the molecule to create free ends; cellobiohydrolases that cleave cellobiose from both ends of the exposed chain to form cellobiose; and, finally, β -glucosidase that generates two glucose molecules from cellobiose. Most cellulases are end-product inhibited, that is, most cellulases are affected by cellobiose [52, 53], while β -glucosidase is particularly sensitive to glucose [54], resulting in an accumulation of these sugars, which slows down hydrolysis (or even stops it completely). Compounds that are generated in the pretreatment step can also have a negative impact on enzymatic hydrolysis. If the liquid fraction from the pretreatment step is replaced or if washed material is used for enzymatic hydrolysis, hydrolysis can be improved [55]. This improvement suggests that other inhibitory compounds than the sugars may play a vital role as inhibitor. Another important factor is the unproductive binding of the cellulase enzymes to lignin, causing the overall catalytic effect to be smaller.

There are many cellulase-producing species in nature, most of them various fungi. The maximum cellulase activity for most fungal-derived cellulases and β -glucosidase occurs at $50 \pm 5^\circ\text{C}$ and a pH of 4–5. During the last decade, much effort has been made to improve the overall activity of the enzymes and the yield of enzymes, but also production itself has been rendered more effective to decrease cost. Independently from ongoing cost-reduction efforts [56, 57], the production cost of enzymes is still rather high and requires further reduction. One way to achieve this is to use a fraction of the feedstock and/or the hydrolysate for on-site enzyme production by fungi or other microorganisms [58].

Some pretreatment methods leave the hemicellulose fraction more or less unaffected calling for additional hydrolysis using hemicellulases. The hemicellulose part of lignocellulosic materials requires other types of enzyme complexes for efficient hydrolysis. Since the raw material differs with regard to the composition of hemicellulose, ideally the enzyme cocktail should be prepared in a way that best meets the demand of the various materials. For example, agricultural residues require xylanases to be present, while it is preferable to have mannanases if the material is softwood.

The hemicellulase system includes among others endo-1,4- β -D-xylanases, which hydrolyze internal bonds in the xylan chain; 1,4- β -D-xylosidases, which attack xylooligosaccharides from the nonreducing end to liberate xylose; endo-1,4- β -D-mannanases, which cleave internal bonds in mannan; and 1,4- β -D-mannosidases, which cleave mannooligosaccharides to mannose. The side groups are removed by a number of enzymes: α -D-galactosidases, α -L-arabinofuranosidases, α -glucuronidases, acetyl xylan esterases and feruloyl, and *p*-cumaric acid esterases [59–62].

Enzymatic hydrolysis of lignocellulosic materials has been studied on a number of substrates and under various conditions [55, 63, 64]. Separate hydrolysis and fermentation (SHF) is an attractive idea since it allows for different conditions during hydrolysis and fermentation, though the choice between SHF and simultaneous saccharification and fermentation (SSF, which is described in detail below) has to be made after economic optimization. It is possible to have a higher temperature during hydrolysis to benefit from the higher activity of the enzymes at elevated temperatures. However, it is important to note that the stability of the enzymes is affected by temperature. It has been shown that it can be favorable to operate at lower temperatures to reach higher yields of sugars. For spruce the optimal temperature was found to be dependent on both residence time and pH, and the maximum degree of cellulose conversion, 69.2%, was obtained at 38°C and pH 4.9 for a residence time of 144 h [65]. The decision regarding maximum reaction rate, optimal stability, and residence time has to be made based on economic considerations. It is also desirable to operate at high solids content to reach sugar concentrations that will result in ethanol concentrations around 4%. However, increasing solids concentrations create technical problems, since it can be difficult to mix the material efficiently, especially in the initial phase of hydrolysis, when the viscosity can be very high [66, 67, 110].

Fermentation of Sugars

Fermentation is performed using a microorganism, usually yeast, which converts sugar to ethanol. The yeast *Saccharomyces cerevisiae* (sometimes referred to as baker's yeast) is today the prime choice in industrial

ethanol production from starch and sugar. It is a very robust microorganism, which has a high ethanol tolerance and is also rather tolerant to inhibitors produced during pretreatment of biomass. It has also a high ethanol productivity (up to $1.3 \text{ g g}^{-1} \text{ cell mass h}^{-1}$) and yield (higher than 0.45 g g^{-1} at optimal conditions) [68]. The main drawback is that it only ferments hexose sugars (i.e., glucose, mannose, and, under certain circumstances, galactose), but is not able to ferment the pentose sugars, xylose and arabinose, which are present in all hemicelluloses, especially in hardwood and agricultural residues (Table 4). There are naturally occurring yeasts (like *Pachysolen tannophilus*, *Pichia stipitis*, and *Candida shehate*) and bacteria (like *Escherichia coli*, *Klebsiella*, *Erwinia*, *Lactobacillus*, *Bacillus*, and *Clostridia*) able to utilize pentoses, but these have other drawbacks (e.g., less tolerance for ethanol and inhibitors, lower fermentation rate, and a need for rigorously controlled aeration), which make them less suitable for industrial applications [69, 70].

A lot of effort has been devoted to the development of efficient xylose-fermenting microorganisms [71, 72], as xylose is by far the most abundant pentose sugar, but there is also research going on to develop the arabinose fermentation [73, 74] as well as on genetically modified *S. cerevisiae* [12, 75, 76].

Genetic modification of *S. cerevisiae* has got a lot of attention due to the attractive properties of this yeast and its abundant use in industry. *S. cerevisiae* can naturally ferment xylulose; so in order to make it also ferment xylose, a pathway for conversion of xylose to xylulose has to be introduced. This can be done in two ways: either by introducing genes encoding for xylose isomerase (XI) from bacteria and fungi [77–79], which converts xylose to xylulose in one step, or by introducing genes encoding for xylose reductase (XR) and xylitol dehydrogenase (XDH) from fungi [80, 81], which first reduces xylose to xylitol and then xylitol is oxidized to xylulose.

Also, the endogenous XKS1 gene encoding xylulokinase (XK) has to be overexpressed to obtain significant xylose fermentation [81].

The uptake of xylose in *S. cerevisiae* is performed by glucose transporters, which have about two orders of magnitude lower affinity for xylose than for glucose [70] resulting in competitive inhibition of xylose

uptake by glucose. A lot of research has been carried out on transport proteins and introduction of various sugar transporters to increase the uptake of xylose [82]. The presence of a small amount of glucose increases the xylose uptake [83]. This has also been shown in recent SSF studies, with co-fermentation of xylose and glucose, where a slow release of glucose, thus maintaining it at low concentration resulted in increased uptake and utilization of xylose [84–86].

Another challenge in fermentation of lignocellulosic hydrolysates is the presence of various compounds present in the hydrolysate that are inhibiting to the microorganism. These compounds comprise degradation products formed during pretreatment (like furfural, HMF, formic acid and levulinic acid, and phenolics) as well as compounds present in the biomass (like acetic acid and extractives) [87]. The concentrations of these and all other inhibitory substances in the fermentation step depend on the configuration of the preceding process steps.

The inhibitory effect can be overcome by detoxification of the hydrolysate before fermentation. There have been many chemical and physical methods proposed that reduce the concentration of inhibitors and improve the performance in the fermentation step.

Treatment with $\text{Ca}(\text{OH})_2$ (so-called overliming), ion-exchange treatment, and steam stripping may increase the fermentability significantly but may also result in some sugar loss [88, 89]. This will also increase both the capital and running costs.

Another approach is to make the yeast more tolerant, by adaptation to the hydrolysate, and to design the fermentation procedure so that the concentrations of inhibitors are kept at a low level. Cultivation of *S. cerevisiae*, both natural strains and genetically modified strains capable of fermenting xylose, on hydrolysates of steam-pretreated spruce containing inhibitors have resulted in higher ethanol yield and productivity from the same hydrolysate than cultivation on pure sugars [90, 91]. The other approach is to run the fermentation in a fed-batch mode and feeding the hydrolysate at a rate that makes it possible for the yeast to detoxify the hydrolysate in situ [92]. Detoxification occurs when carbonyl compounds – like in furans and phenolics – are reduced to the corresponding alcohols, which are less inhibitory to yeast [93]. In such cases, the fermentation productivity

will be a function of the inhibitor concentration, the conversion capacity of the yeast, and the quality of the process control.

One inhibitor usually present in hydrolysates is acetic acid, formed from the acetyl groups present in most hemicelluloses. Acetic acid has a pK_a of 4.75, which is close to the pH of fermentation and therefore a significant amount is in undissociated form that can diffuse through the plasma membrane, and may dissociate inside the cell. This has an intense inhibitory effect on growth of *Saccharomyces cerevisiae*, but leads to an increased ethanol yield at low concentrations, up to 6 g/L [31, 94]. In order to avoid the drop in intracellular pH, the cell must pump out protons using the plasma membrane ATPase. To achieve this, the cells have to produce more ATP, which in anaerobic conditions is done by producing more ethanol and thus resulting in increased ethanol yield [30]. Increased ethanol yield has also been noted in the presence of furfural at low concentrations [95]. At higher concentrations of acetic acid (above 10 g/L), the ethanol yield is decreased while initial furfural concentrations below 5 g/L can be acceptable for fermentation; however, at higher concentrations severe inhibition may occur, which reduces the ethanol productivity [96].

Another option to run the fermentation is by continuous fermentation with several fermentors in cascade. In continuous fermentation, the yeast is retained in the fermentor either by running at a dilution rate below the growth rate of the yeast or by recycling the yeast. This would be beneficial as the yeast gets adapted to the inhibitors present in the hydrolysate. Furthermore, it results in reduced labor costs and reduced fermentor downtime for cleaning and filling, as well as in higher volumetric productivity (in case cells are recycled) compared with batch fermentation [97].

Process Intensification

One of the most crucial factors in process intensification of the ethanol production process is to run the process at as high dry-matter concentration as possible, which leads to decreased size of equipment as well as to reduced energy demands. This leads to less material being handled and less water to be removed in the downstream processing, which has a significant effect on capital and running cost [98, 99]. Figure 7 shows

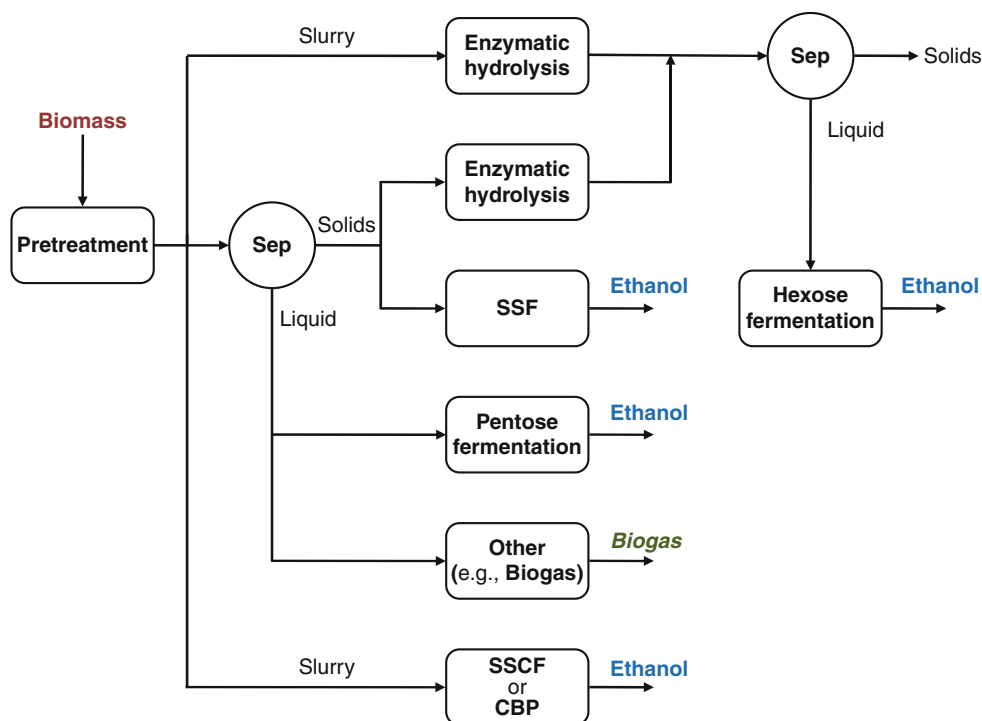

Bioethanol from Celluloses. Figure 7

Comparison of the overall energy demand and total production cost as function of the solid concentration

a comparison of the overall energy demand and total production cost as function of the solid concentration in the SSF for ethanol production from spruce [100] assuming that an increase in dry matter does not affect the conversion yield. Similar relationships were found for corn stover and salix [101, 102].

However, high dry matter leads to problems related to heat and mass transfer in the conversion steps (i.e., pretreatment, enzymatic hydrolysis, and fermentation (or SSF)) as well as higher concentration of inhibitors in the biological steps, as is outlined below. The concentrations of various inhibitors depend though on how the process is designed as can be seen in Fig. 8. In process configurations where the liquid after pretreatment is separated and used for other purposes, the effect of inhibitors on SHF or SSF of the solids diminishes (e.g., IBUS process [103]). The liquid could then be used for other applications (e.g., biogas production) where it may be diluted without negative effects as the product is recovered from a gas phase, where the product concentration is not affected by the substrate concentration in the liquid. Lower inhibitor concentrations can also be achieved by using pretreatment methods that do not create degradation products keeping in mind that several inhibitors, like acetic acid and extractives, are present in the lignocellulosic material and are difficult to avoid.

Another important way to reduce the energy demand in the process and reduce capital cost is by process integration, that is, by using as few process steps as possible. Simultaneous saccharification and

Bioethanol from Celluloses. Figure 8

Various process configurations and some potential products

fermentation (Fig. 8) can be seen as one type of integration that results in both lower energy demand and lower capital cost. SSF has been widely used also for industrial starch-based fuel-ethanol production. By performing the enzymatic hydrolysis and fermentation in the same reactor, the sugars formed by enzymatic hydrolysis are converted by the yeast as soon as they are released. This maintains a low concentration of sugars in the broth which alleviates the end-product inhibition of the cellulases and also diminishes the risk for infections. Another advantage is the capability of the yeast to partly detoxify the slurry [55]. These two effects result in an increased enzymatic hydrolysis productivity compared with enzymatic hydrolysis performed at higher temperatures. This results in higher overall ethanol productivity, which means a lower total reactor volume. It has also been shown in several studies that the ethanol yield is higher after SSF than after SHF both for softwood and agricultural residues [104, 105]. However, the development of new cellulases that are less end-product-inhibited may change this situation in the future.

Another advantage of SSF is that glucose does not need to be separated from the lignin fraction following a separate enzymatic hydrolysis step, thereby avoiding not only a potential loss of sugar but also excessive washing, which dilutes the sugar stream. After the SSF, the slurry is taken to a distillation step where ethanol is distilled off, with negligible loss of ethanol in the remaining stillage stream, and the lignin is then separated by filtration.

The main drawback with SSF is that the yeast after SSF is difficult to recover as it is mixed with the residual solid (i.e., mainly lignin) and also that the optimal temperature and pH for enzymatic hydrolysis and fermentation differ. In spite of this, SSF is in many studies considered as a better option than SHF for several raw materials investigated. The use of SSF is also cost effective, since it reduces the number of reactors [106].

Other studies on SSF have aimed at decreasing the enzyme and yeast concentrations and varying temperature and pH. The enzymes are either produced on-site, which results in less substrate available for ethanol production and thereby a lower overall ethanol yield, or

purchased and thereby add to the cost of chemicals. The yeast will most probably be cultivated using the hydrolysates after pretreatment, in order to adapt it to the hydrolysates. A higher yeast concentration will thus lead to a lower overall ethanol yield. As the rate of the enzymatic hydrolysis is rate-limiting in most SSF experiments, the yeast concentration can be lowered [8, 101, 107] but should not be too low to avoid a stuck fermentation.

When both pentoses and hexoses are fermented together in SSF, the process is referred to as SSCF (i.e., simultaneous saccharification and co-fermentation). In this case, the whole slurry from pretreatment is fed directly to SSF, which reduces the number of process steps compared to separate pentose fermentation and SSF. SSCF can also lead to better utilization of sugars. Studies [84, 85, 108] have shown that the utilization of xylose, using pentose-fermenting yeast, was improved when SSF was used for slow release of glucose, which facilitated the uptake of xylose, compared with when all glucose is available from the start, which is the case in traditional SHF. The slow release may be controlled either by the enzyme dosage, by the temperature during SSF, or by a combination of both [108]. However, it may be difficult to control the slow release of glucose in full scale, so it will be necessary to perform tests in pilot-plant size to evaluate the concept.

Still another option for an even more integrated process is to perform enzyme production, enzymatic hydrolysis, and fermentation in a single reactor, so-called consolidated bioprocessing (CBP) [109]. CBP has the potential for lower bioethanol production costs due to simpler feedstock processing, lower energy inputs, and lower capital cost than separate hydrolysis and fermentation processes. However, this requires a microorganism that produces all the required enzymes and ferments all sugars. This could either be done by engineering bacteria that naturally utilizes cellulose, like *Clostridium cellulolyticum* or *Clostridium thermocellum*, and improve the ethanol production in those or to genetically modify naturally good ethanol-fermenting microorganisms (like the yeast *S. cerevisiae*) to express heterologous cellulase systems. Both approaches have been investigated but to date no microorganisms are available, which are sufficiently effective and the concept is subject to further research.

To avoid problems with mass transfer in enzymatic hydrolysis, SSF, SSCE, or CBP, a short prehydrolysis can be performed where the material is partly liquefied and the viscosity drops. This may be performed in specially designed reactors. One example [110] has been capable of liquefying pretreated wheat straw at solids concentrations up to 40% (w/w) by the use of enzymes. Another way of handling both the mass transfer and inhibitor problems in the biological conversion step, like SSF, is to run in a fed-batch mode.

In recent years, significant progress has been made in running SSF at higher solids loading both by using adaptation of yeast or fed-batch procedures to overcome the effect of inhibitors. Final ethanol yields higher than 70% of theoretical, based on total hexoses and pentoses, and final ethanol concentrations around 4% (wt/wt) can be expected [108].

In case the liquid after pretreatment is removed before the SSF step, that is, using only the cellulose for ethanol production, while the hydrolysate containing the hemicellulose sugars and the inhibitory compounds are used for other purposes (like biogas), the ethanol concentration in SSF can be even higher. An ethanol concentration higher than 6 wt-% has been demonstrated in a combined prehydrolysis and SSF of pretreated wheat straw although the running time was higher than 200 h [103].

The most obvious way to reduce energy demand is by heat integration of steam-requiring process steps. By running the various process steps at different pressures, it is possible to use the secondary steam obtained from the equipment run at high pressure to heat an equipment run at low pressure. This could include integration of the distillation step with the evaporation plant, increasing the amount of distillation columns, or increasing the number of units in the multiple-effect evaporation unit [111]. A somewhat different concept is to introduce mechanical vapor recompression in distillation and/or evaporation [111].

Another option is to replace energy-demanding process units with a less energy-demanding process step. One option that has been proposed to take care of the stillage stream is to evaporate it and concentrate the nonvolatiles to dry-matter content above 50–60 wt-% and then burn the residue in a boiler to produce heat for the ethanol process. Evaporation of the stillage is very energy demanding [100] and is performed mainly

as a wastewater treatment step. The energy obtained from combustion of the concentrated stillage stream is in the same order as the energy needed to perform the evaporation. One option could be to replace evaporation with anaerobic fermentation of the stillage stream for production of biogas. In this way, the energy demand for evaporation can be eliminated and also the capital cost. Both volatile and nonvolatile organic compounds are converted to biogas, which can then be used in the boiler for production of heat and power to the process. Alternatively, the biogas can be upgraded to pure methane to be used as transportation fuel. The amount of biogas that can be produced depends on the composition of the stillage stream and has to be verified experimentally for each specific stillage stream to assure that most of the organics are fermented. Also, the requirement of an aerobic treatment step for final wastewater handling needs to be evaluated. In a couple of studies where evaporation has been replaced by anaerobic digestion, it has been shown that the potential for reducing the energy demand and the ethanol production cost is substantial [112, 113].

External Process Integration

One approach to reduce the production cost for cellulosic ethanol production is to integrate it with another suitable plant (e.g., a combined heat and power plant, a starch-based ethanol plant, a sugar-based ethanol plant, or a pulp and paper mill). The type of plant to integrate with is very much dependent on the biomass that is to be used, the location, and also the process configuration. For instance, in case wood residues are used, it could be suitable to integrate with a CHP plant that is also using forest residues for heat and power production. Part of the solid residue can then be replaced by the lignin fraction available from the cellulosic ethanol plant and the CHP plant provides the ethanol plant with steam and electricity.

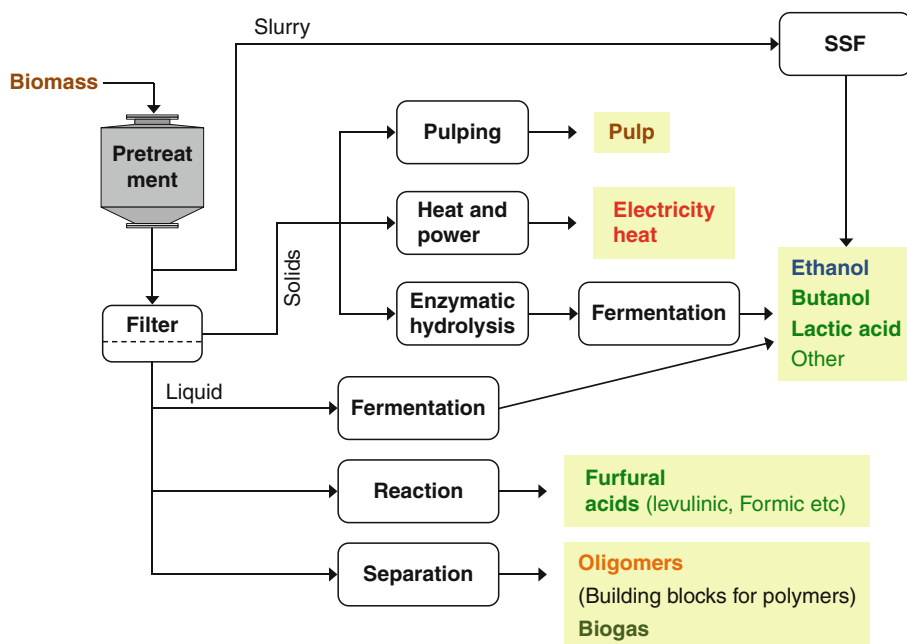

Another option is to integrate cellulosic ethanol production with starch-based ethanol production (e.g., from corn or wheat) to utilize the whole agricultural crop. One benefit is that the raw material is close to the factory and another is that the lignin from the cellulosic part of the material can provide heat and electricity for both processes, that is, both for the first-generation and the second-generation ethanol

plant. Depending on how the integration is performed, it could also help to boost the ethanol concentration resulting from the lignocellulosic process, for example, if the same distillation unit is used for both plants. This will reduce the energy demands in the distillation and the evaporation steps. However, in case the residue from the first-generation plant is to be used as animal feed (DDGS), the integration approach must be carefully chosen to avoid affecting the value of the DDGS. In case the residue is used for biogas production, the integration is easier to implement.

A third option is integration with a sugar-based ethanol production plant (e.g., sugarcane-based ethanol production). The same benefits as for integration with starch-based ethanol production can be achieved.

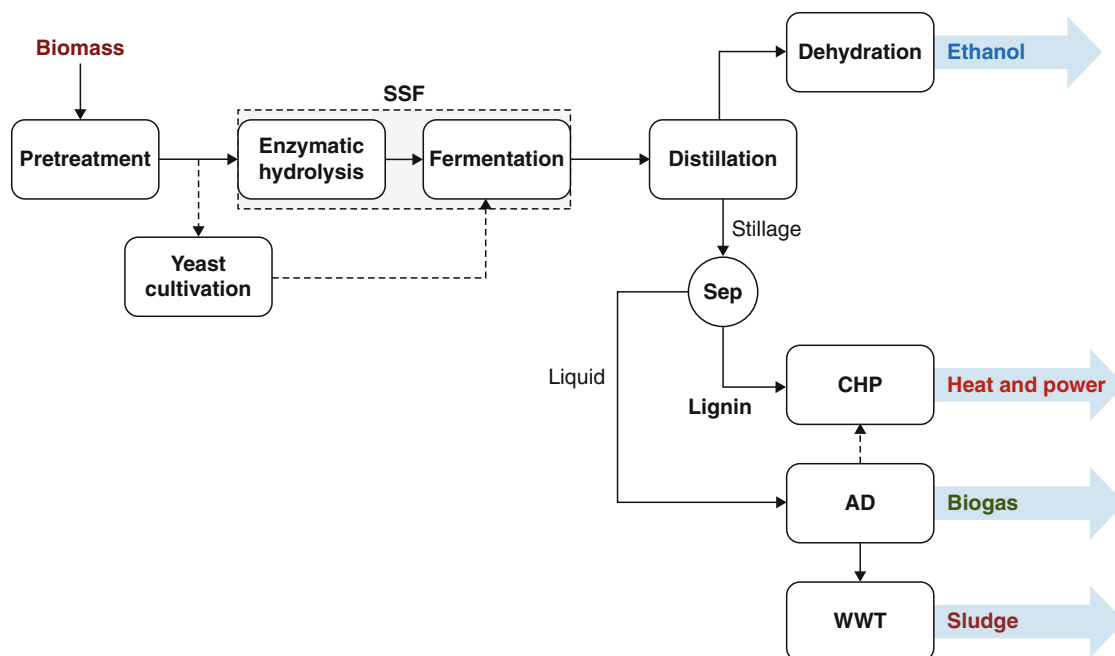

The biorefinery concept, that is, to use the whole crop for production of a variety of chemicals and fuels using chemical and biological transformations, is also an interesting option. Figure 9 shows a variety of products that could be produced when ethanol is produced from either the cellulose fraction only or from both cellulose and hemicellulose. In this case, the income from other products improves the overall process economics.

Integration with Heat and Power Plant Integration of cellulose-based ethanol production with a combined heat and power plant (Fig. 10) has the possibility to reduce the production cost of ethanol. One of the benefits is that the syrup or lignin residue can be used for steam production without prior drying, which reduces the energy demand. This type of integration is even more interesting in case the plants are combined with district heating as the heat of condensation in the flue gases from the CHP can be utilized for district heating. Also the excess heat from the ethanol plant can be utilized for this purpose. Such integration has been shown to increase the energy efficiency and reduce the production cost by up to 20% for conditions prevailing in Sweden [114]. The study was based on ethanol production from 200,000 t of spruce per year. Various options for the utilization of the solid residue formed during ethanol production from spruce, such as the production of pellets, electricity, and heat for district heating, were compared. The overall energy efficiency ranged from 53% to 92% (based on the lower heating values, LHV) with the highest value for

Bioethanol from Celluloses. Figure 9

A selected number of potential products from biomass

Bioethanol from Celluloses. Figure 10

Integration of a cellulose-based ethanol production with a combined heat and power plant

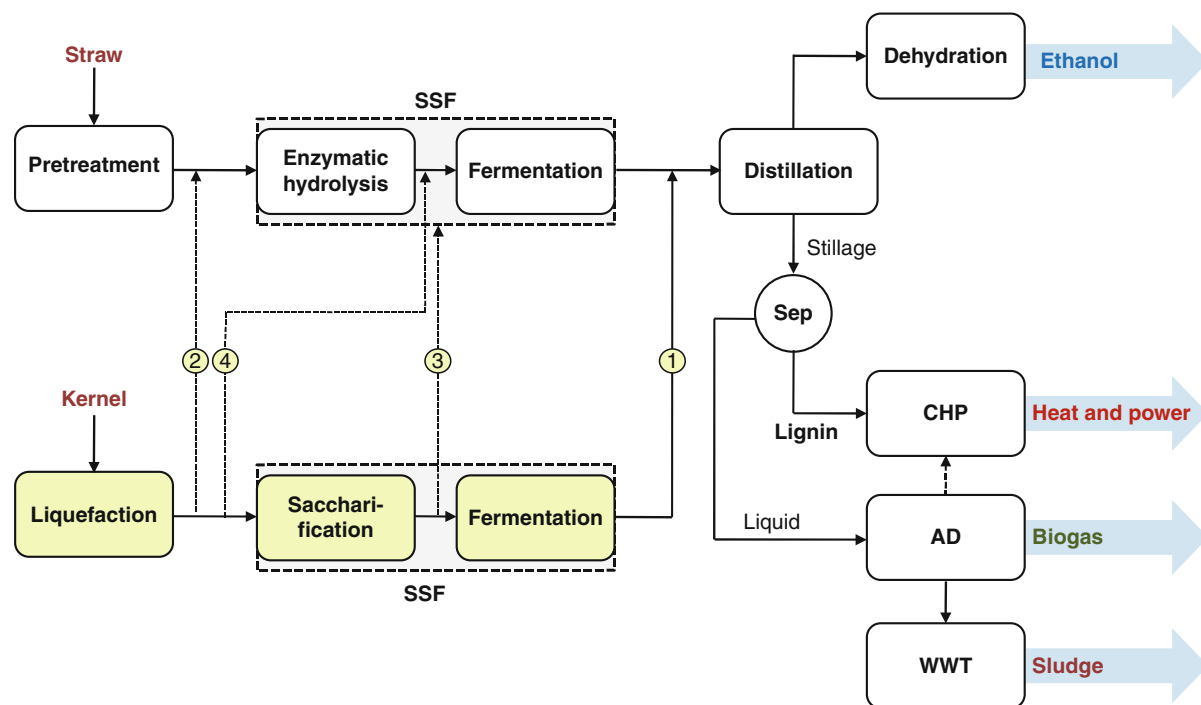

cases with district heating, where a large part of the low temperature waste heat from the process can be utilized. However, this option restricts the location to the vicinity of larger cities of the plant as there must be a demand for the surplus heat. Similar conclusions regarding utilization of waste heat were reached in a study on coproduction of ethanol and electricity from softwood, based on conditions in California [115].

In a recent study on ethanol from spruce [113] several configurations where evaporation of the liquid fraction of the stillage stream from distillation was replaced by anaerobic digestion (AD) followed by aerobic wastewater treatment were investigated. In the best case, the energy efficiency, based on LHV, for the combined production of ethanol and biogas was 59% and the overall efficiency, including the contributions from electricity and district heat, was 92%. This process configuration resulted also in the lowest ethanol production cost. The total ethanol production cost was diminished by 17–22% compared with the base case using evaporation of the stillage stream and burning of the concentrated syrup in the CHP.

Most of the existing pilot and demo scale plants for cellulosic ethanol production are integrated with production of power and steam, mostly using the lignin fraction.

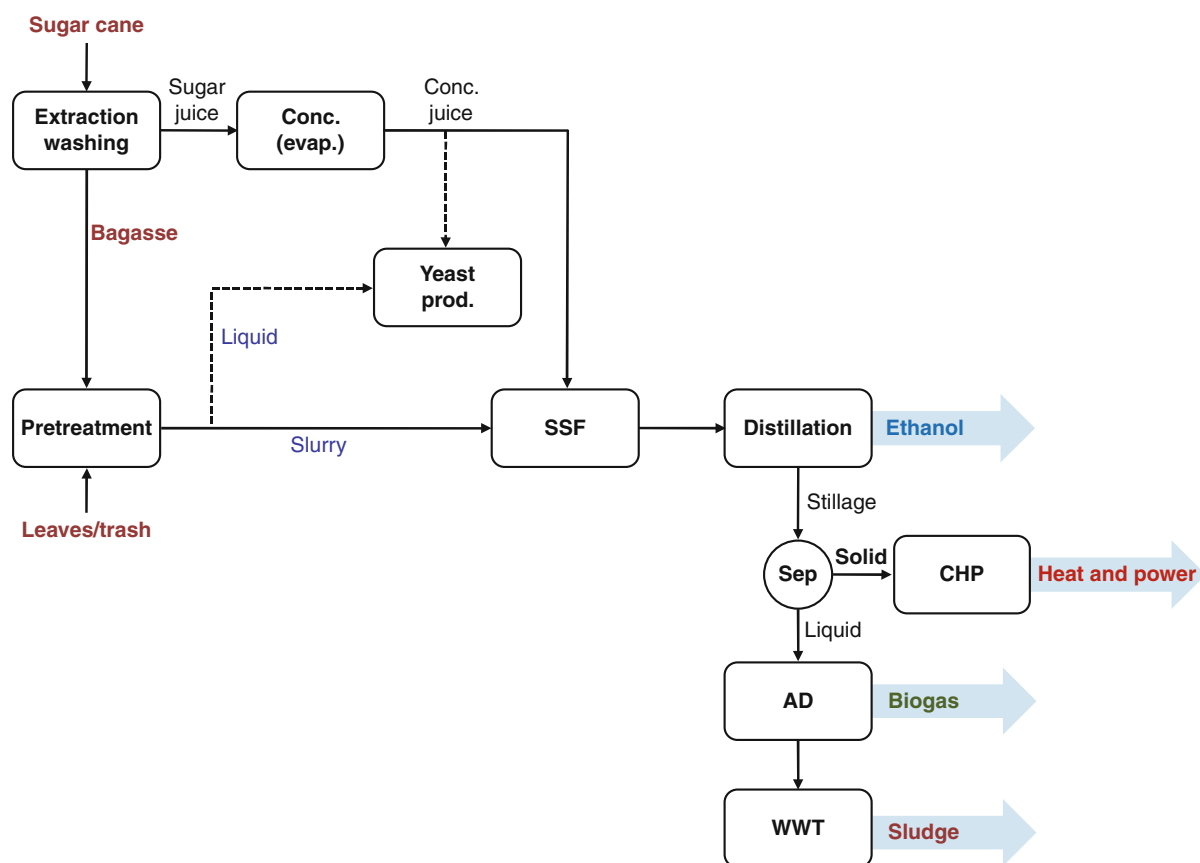

Integration with First-Generation Ethanol Another option is to integrate second-generation cellulosic ethanol production with first-generation starch-based or sugar-based ethanol production to use the whole agricultural crop (Figs. 11 and 12, respectively). Suitable residues are corn stover, corn cobs, corn fiber, wheat straw, and sugarcane bagasse and leaves/trash. There are many possible ways to integrate the processes (Fig. 11) for the starch-based case, and the desired choice of integration is very much influenced by the choice of coproducts.

The absolute lowest degree of integration is to share the heat and power production plant where the lignin residue, and in some cases also biogas, from the second-generation plant is used to provide heat and electricity to both plants. This is perhaps the most obvious integration in corn-based ethanol plants in the USA where the corn is used to produce several different

Bioethanol from Celluloses. Figure 11

Integration of starch-based and lignocellulose-based ethanol production

Bioethanol from Celluloses. Figure 12

Integration of sugarcane-based and lignocellulose-based ethanol production

coproducts, besides ethanol, and where most of the plants are using natural gas for heat and power production. In case this is replaced by heat and power from the cellulosic material, it will improve the sustainability of these plants. Another option, at a low integration level is to use a combined distillation plant (option 1 in Fig. 11). The two processes would have separate and dedicated equipment for pretreatment, hydrolysis and fermentation. As it is usually difficult to reach high sugar and ethanol concentrations in the second-generation ethanol production, while starch- or molasses-based ethanol production require dilution of the sugar, the latter could be used to boost the second-generation ethanol stream to reach ethanol concentrations well above 4–5 wt-%. This would result in a decrease of the critical energy demand in the combined distillation

step compared with distillation in two units well below 4 wt-% ethanol (Fig. 13).

The possibility for integration in the upstream direction increases when both first- and second-generation plants are designed and erected simultaneously. Figure 11 shows some options [2–4] where material streams are combined further upstream. This could reduce not only the equipment cost but also the energy demand. Integration may also alleviate some of the inhibitory effects occurring from formation of toxic compounds in the pretreatment step. If the process streams are mixed prior to fermentation the lignocellulosic streams will be diluted by the starch- or sugar-based streams. The integration may in some cases also lead to higher ethanol yield from the first-generation plant. In a study where pretreated wheat straw was

Bioethanol from Celluloses. Figure 13

Energy demand in the distillation step, where ethanol is concentrated to 94 wt-%, as a function of the ethanol feed concentration. The step was assumed to consist of two stripper columns (25 trays each) and a rectification column (35 trays) heat integrated by operating at different pressures. The inlet feed temperature was increased from 80°C to the boiling temperature before entering each stripper column

mixed with wheat starch, a higher ethanol yield as compared with using either only starch or only wheat straw was obtained using SSF [116]. This was probably due to the stress on *S. Cerevisiae* caused by weak organic acids present in the hydrolysate of steam-pretreated wheat straw. It is also easier to reach a high ethanol concentration using such a mixture than when using wheat straw only as a raw material. The use of the wheat starch, coming from wheat flour, is rather rich in nutrients, which could also contribute to decrease the amount of additional nutrients needed in SSF of wheat straw.

Figure 12 shows a fully integrated ethanol production process for utilization of the whole sugarcane plant. In this case, the sugarcane bagasse (i.e., the residue of the cane after extraction of sucrose) is already on site at the ethanol mill. In many sugarcane ethanol plants, the bagasse is used to provide steam for the process and to cogenerate electricity, but by using a part of it for ethanol production the value chain can be increased [117]. Another option is to also use the leaves of the sugarcane, which in many cases today are burnt on the field creating an air pollution problem. In Brazil, which is a large producer of sugarcane ethanol, the government is becoming more restrictive regarding

burning of residue in the field [118]. The development of more efficient burners [119–121] will also allow more effective use of these resources.

To summarize, the integration of first- and second-generation bioethanol production results in higher ethanol yield, lower energy demand, and lower production cost than by using a stand-alone second-generation ethanol production. To define the most optimal way of integration requires detailed studies (e.g., by flow-sheeting calculations based on reliable experimental data).

Future Directions

Substantial progress has been achieved in the field of lignocellulosic fuel-ethanol production and several pilot and demo plants have been built the recent years [122]. However, there are still several challenges remaining before reaching a mature industrial technology. Some of the most important challenges are:

- To produce ethanol at a high concentration. The most obvious is to perform enzymatic hydrolysis or SSF at high dry-matter concentration. This requires improvement of enzymatic hydrolysis with efficient enzymes, reduced enzyme production cost, and novel technology for high solids handling. Another important factor is to utilize all the sugars available in the pretreated material, that is, either including pentose fermentation or to produce some other energy product like biogas. The former will lead both to a higher ethanol concentration and to a lower production cost, while the latter results in a facilitated ethanol production from hexoses.
- The increase in concentration of inhibitory compounds with increased dry matter may lead to a decreased ethanol yield. To cope with this, an option is to separate the solid and liquid fractions and only use the solid fraction (i.e., the cellulose) for ethanol production. The liquid could then be used for other applications (e.g., biogas production) where it may be diluted without negative effects in the product recovery as the biogas is obtained in the gas phase.
- Development of robust fermenting organisms, which are more tolerant to inhibitors and ferment both pentoses and hexoses in the raw material in concentrated hydrolysates with high yield, at high

productivity and with high ethanol concentration. The co-fermentation of pentoses and hexoses will lead both to a higher ethanol concentration and to a lower production cost.

- Extension of process integration to reduce the number of process steps and the energy demand and to reuse process streams to eliminate the use of fresh-water and to reduce the amount of waste streams.
- Process integration with other types of industrial processes, for example, a combined heat and power plant or first-generation ethanol plant, which will reduce the production cost further. This may result in higher ethanol concentrations to the distillation step compared with a stand-alone second-generation plant.

One of the most important issues is to verify all process steps in an integrated way in pilot and/or demo scale. These plants should provide data for full-scale ethanol production and at the same time define new challenges for further research. The step from pilot- and demo-scale production of lignocellulosic ethanol to competitive full-scale production requires further reduction of the production cost. In pilot and demo scale, it is important to prove the whole process for longer periods of time with variation in raw material, which can be due to normal variations in crops due to where it is grown and the climate as well as by changes during storage. High accessibility and verification of yields and productivities obtained in lab and bench scale has also to be achieved, especially for critical process steps as pretreatment and SHF or SSF. Also more technical issues like separation of lignin and the influence of process integration and recycling of process streams on fouling. The qualities of products and coproducts as well as wastewater treatment are other important factors.

A conclusion to be drawn is that there is a significant potential of improvement and development. The production processes can be far more efficiently designed in the future as compared with prevailing concepts considering individual process steps, process configurations, and a huge number of combinations of process integration options.

This complexity and large number of design options could be considered both as positive and negative features when it comes to industrial implementation. The positive side is that the production process

can be optimized for the specific local conditions, depending on available raw materials, heat sinks for use of district heating, demand for biogas as vehicle fuel, and other existing facilities to integrate with. The ethanol production system can then be designed to optimize the overall energy efficiency and profitability for the entire system. The negative side is that the high complexity requires a huge amount of knowledge for development of the most optimal production systems, which is not yet available.

To conclude, lignocellulosic ethanol has a promising role to play in the development of efficient and sustainable biofuel production systems in the future, but this requires improved knowledge and competence among all the different actors involved in this process. Furthermore, a more integrated work is needed between different research fields, such as process development and configuration and energy and environmental systems analysis (e.g., life cycle assessments) to optimize future production systems in a most efficient way regarding an economic, energy efficient and environmental sound perspective.

Glossary

Alcohol Often used trivial name for ethanol, in chemistry it describes the class of alcohols including also methanol, butanol, etc.

Bioethanol Product of a fermentative process used mainly as a fuel from renewable substrates in comparison to the use of fossil fuels.

Ethanol Chemical name of an alcohol with the molecular formula $\text{CH}_3\text{—CH}_2\text{—OH}$ and is the same chemical substance as bioethanol and has other synonyms like bioethanol, ethyl alcohol, pure alcohol, or drinking alcohol.

DDGS Animal feed called “distillers’ dried grain with solubles.”

Fermentation Process step which produces ethanol and CO_2 as product.

Liquefaction Enzymatic process step using amylases to cut the starch chains into oligosaccharides.

Saccharification Enzymatic process step using beta-amylases and glucoamylases to cut oligosaccharides into fermentable sugars.

Starch Starch is a very important part of the human food in sources like wheat, maize, rice, potatoes, and many other plants and is also a source of sugars for the fermentation.

Thin stillage Liquid stream received from the decanter containing dissolved nutrients and salts.

Yeast *Saccharomyces cerevisiae* is the organism used in the ethanol production industry.

Wet cake Solid-rich stream received from the decanter containing nutrients like proteins.

Definition of the Subject and Its Importance

Ethanol is a very interesting chemical compound which can be used in different applications such as drinking alcohol in beverages as well as in chemicals, pharmaceuticals, and biofuels. Production of alcoholic beverages based on biomass containing sugar can be assumed as old as human civilization. The production of ethanol from starch using a fermentation process started most probably in beer-producing countries approximately in the twelfth century. The production of “pure” ethanol is also a very long known process. The development of more efficient distillation processes in the nineteenth century led to large increase in industrial trade of ethanol. The largest amount of the industrial ethanol was still used for alcoholic beverages. But also other applications like the use in the chemical industry, as lamp fuel and as a fuel have been exploited.

The use of ethanol as a fuel started at the beginning of the twentieth century, the time the Ford Model T could run since 1908 on ethanol. With the fast development of the petroleum industry, the use of ethanol as a fuel was negligible till late twentieth century. Due to price increases of raw oil and also environmental concerns, ethanol showed a revival as a fuel based on renewable substrates like sugar and starch or even celluloses. For fuel applications, mainly the name bioethanol is used but the whole ethanol production chain including also the agricultural growth of the substrate has to be taken into account to prove that the produced ethanol really shows significant environmental benefits compared to fossil fuels.

This entry concentrates on bioethanol from starch only. Bioethanol from other substrates like sugar and lignocellulosic material will be discussed in the respective entries. Bioethanol from starch reached 2009 a share of about 60% of the total worldwide production. Starch as a substrate is mainly used in the USA and Europe. Since the worldwide need for transportation fuels is steadily increasing, there is a need for a further increased production of sustainable produced biofuels like bioethanol. Since starchy substrates are also the basis for human nutrition and animal feeding, it is very important to balance the use of these very valuable materials. A large amount of the worldwide produced grain crops are used for animal feeding. Using these grain crops for bioethanol production, about the same amount of animal feed is produced as a very important second product. This allows a combination of animal feed production with bioethanol production and is already installed in many bioethanol-producing plants worldwide which use grain crops as substrate. Taking this fact into account, it will be possible to increase the bioethanol production based on grain crops further to a certain extent keeping the whole system of bioethanol production combined with human nutrition and animal feeding into account. Further significant increase in bioethanol production will be achieved if combinations of starch and lignocellulosic substrates or lignocellulosic substrates only are fully economically developed. Details on lignocellulosic substrates for bioethanol production can be found in the respective entries.

Introduction

Production of bioethanol from starch is, in addition to the production from sugar, also a very well-known process. The technology and process steps needed for starchy materials differ compared to sugar-containing substrates in the substrate treatment section of the bioethanol plant and in the stillage treatment processes (Fig. 1). After milling of the starchy substrates two enzymatic process steps, the liquefaction and the saccharification, are needed to receive a fermentable sugar solution. The fermentation of this sugar stream can be done traditionally using yeast. The further downstream process steps are distillation and rectification of the liquid stream to increase the concentration of the bioethanol. The final product quality in terms of allowed water content in the bioethanol is reached normally by using an adsorption process. The stillage received from the distillation or beer column is further treated in a decanter to separate a wet cake stream and a thin stillage stream which can partly be recycled to mash preparation or concentrated in an evaporation process. After concentration, the thin stillage is mixed with the wet cake and together tried to produce an

animal feed as a second product the so-called distillers' dried grain with solubles (DDGS).

Currently the world bioethanol production is based approximately to 40% of sugar crops and 60% of grain crops as feedstock. Sugar is mainly used as substrate in Brazil and other sugar-producing countries. Starch as main substrate for the bioethanol production is used in the USA and Europe and also in many other countries. In Europe, also sugar from sugar beet processing like molasses are used to some extend as co-substrate for bioethanol production depending on the price of the substrate.

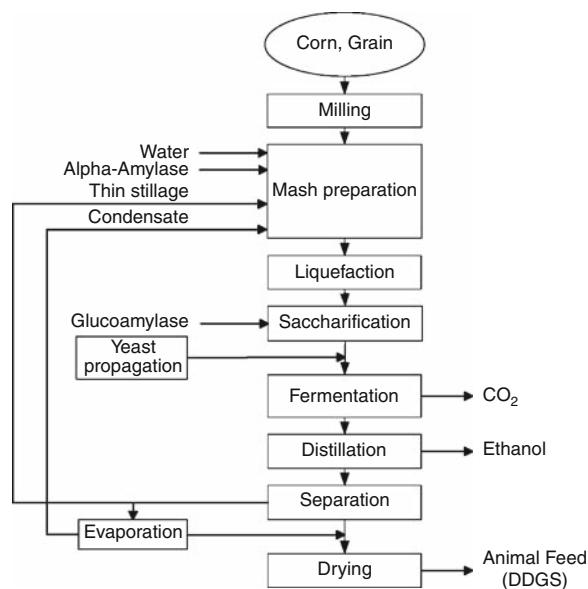

State of the Art of the Production

Raw Materials Containing Starch

Starch is a polysaccharide consisting of a large number of D-glucose molecules which are linked by glycosidic bonds. Green plants can produce D-glucose from carbon dioxide (CO_2) from the atmosphere and water via photosynthesis using sunlight. D-glucose is used from the plant for growing. Access amount can be stored in the plant as starch in the form of granules. Within the stored polysaccharide glucose can be in the linear form via 1,4-alpha glycosidic bonds (amylose) as well as in the branched form via 1,6-alpha glycosidic bonds (amylopectin). In different plants, the starch content of amylose can vary between 20% and 25% and a respective content of amylopectin from 75% to 80% [1]. Within the bioethanol process, mainly the amylopectin content of the starch is responsible for the strong increase of viscosity during the treatment which has to be taken into account in designing the process.

For the bioethanol process, a broad variety of starch-containing plants are used. The choice of feedstock varies a lot in different regions of the world. Within the US Corn Belt, maize (or corn) is the main feedstock. In Europe, Canada, and many other regions wheat, corn, and other cereals like barley, rye, and triticale (a hybrid of wheat and rye) are used for bioethanol production.

Other interesting feedstocks are potatoes, cassava, and sorghum. Potatoes are grown in many countries. The main disadvantage is the high water content (Table 1) which results in high transportation costs

Bioethanol from Starch. Figure 1

and losses during storing. Cassava with alternative names yucca, tapioca, or manioc is a tropical plant developing starch-containing roots. As a fresh root, it has high water content. Therefore, long-term storage without drying is barely possible. But drying needs separate handling and treatment. In Table 1, the composition of starchy feedstock is listed.

The bioethanol-producing potential from the listed feedstock is given in Table 2 [3]. An average bioethanol yield has been assumed and also the DDGS product yield is listed. For potato and cassava chips, usually the wet cake is further used and not dried.

From Table 2, it can be seen that the highest bioethanol yields from 1 t feedstock (as is basis) is achieved from cassava chips, sorghum, and maize followed by wheat. The yield of animal feed (DDGS) also varies with the substrate used. Substrates giving the lower ethanol yields give higher animal feed yields

like barley, rye, wheat, sorghum followed by maize showing nearly the same yield for bioethanol and animal feed.

Processing of Starch-Containing Raw Materials

To achieve the highest bioethanol amount from the feedstock used, it is important that the optimal conditions are adjusted for the yeast. Hence, it is necessary that sugar and minerals are available in an ideal concentration. Additionally, the temperature and pH need to be kept in the optimal range for the microorganism.

In general, the design and mass balance of bioethanol plant based on corn and wheat is similar and both feedstocks can be used in the same plant if designed properly. Special attention need to be addressed to the fact that in wheat the content of

nonstarch polysaccharides is higher than in corn. Especially the pentosane and glucan are responsible for the increase of viscosity and fouling tendency in the process which leads to reduced heat transfer rates in the heat exchangers. To reduce or avoid problems in the process, special enzymes for reducing the chain length of these substances to make them soluble in the process stream need to be applied. Higher viscosity of the mash need to be controlled by solid concentration which might lead to lower ethanol concentration after the fermentation which results in a higher energy demand of the whole process. Also during processing of wheat the lower lipid concentration combined with higher raw protein content (approximately >13%) leads to an increased foaming tendency during fermentation which might need dosing of antifoaming agents [2]. In Fig. 2, a schematic layout of a dry-mill bioethanol process with DDGS production is shown.

In the following entries, the different process steps are discussed in detail.

Grinding Process The first step in the production of bioethanol from starch is the milling (grinding) of the feedstock. Two different processes are possible: the wet-mill or the dry-mill process.

- In the past, wet-mill processes were often used since several valuable products like corn oil, gluten meal, various starch qualities, and feed products can be derived besides bioethanol which is not the main product during this process [4]. Wet-mill plants are more complex and need approximately 40% more investment than a comparable dry-mill plant because the whole by-product separation equipment must also be installed [5].
- The dry-mill process [6] is optimized for the production of bioethanol and animal feed called distillers' dried grains with solubles (DDGS). The dry-mill process needs less energy per ton of bioethanol produced. Nowadays, most bioethanol for the use of fuel is coming from a dry-mill process. For this process, the corn or grain is ground into coarse flour which is further processed (Fig. 2).

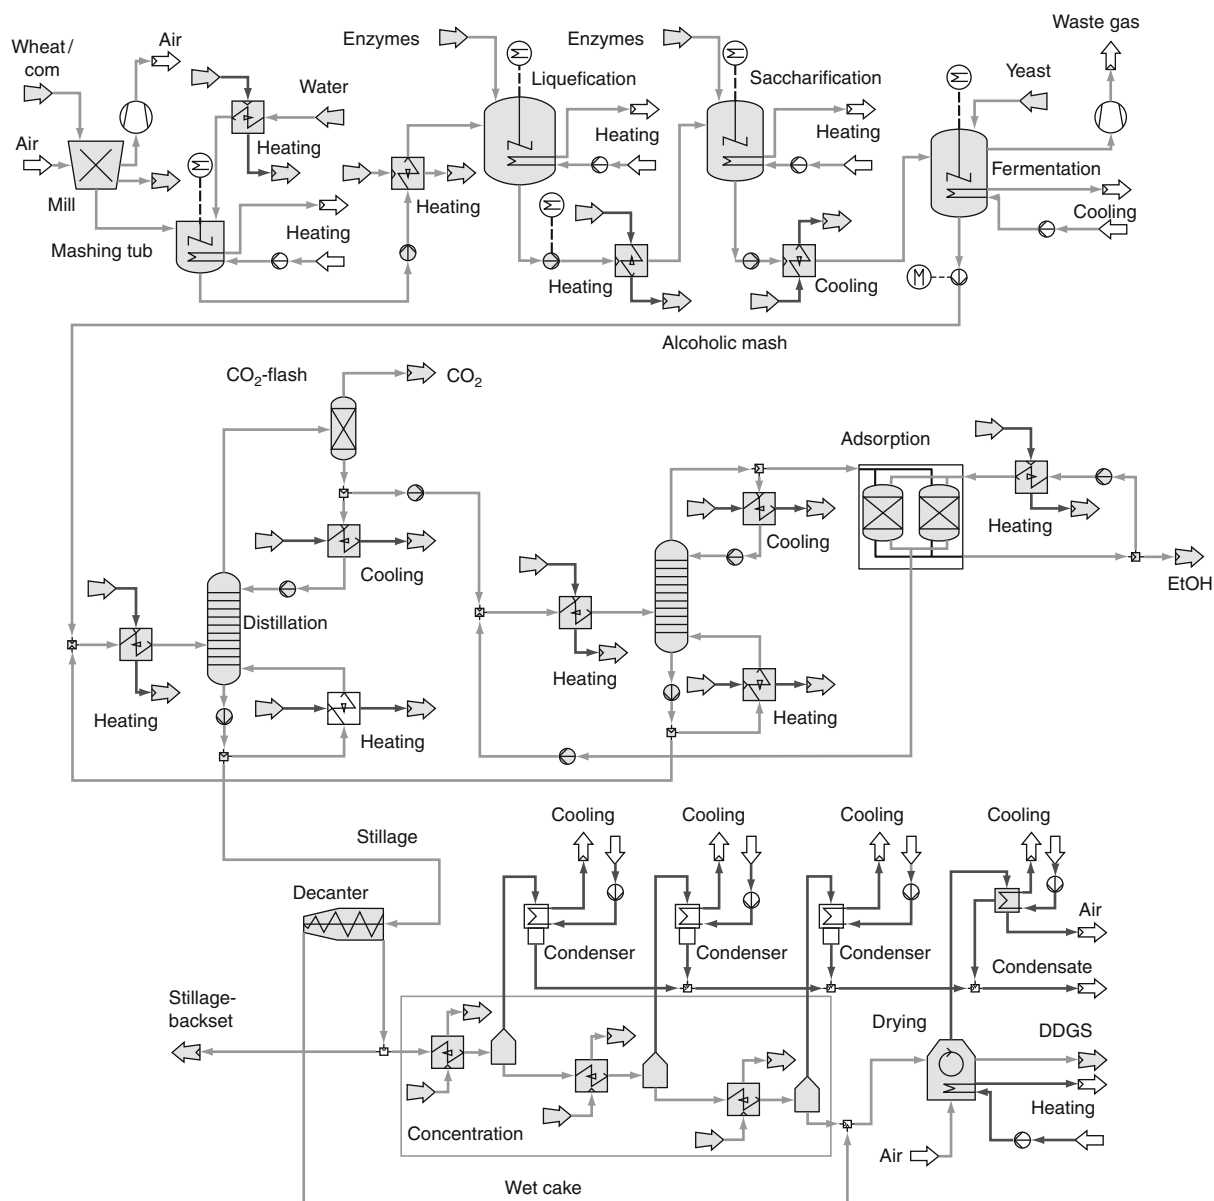

In a standard dry-mill process, the grain is feed by gravity to the mill and grinded usually using a hammer mill. The particle size of the meal has an important

influence on the enzyme effectiveness and also on the ethanol yield. The ground meal is mixed in the mashing tub with water (fresh or recycle streams) and alpha-amylase to prepare the mash as can be seen in Figs. 1 and 2.

Liquefaction Process For the nearly complete use of starch in a technical bioethanol production, an enzymatic process step using amylases is obligatory. Therefore, two different groups of starch-degrading enzymes are needed. Alpha-amylases are responsible for the fast break down of the viscosity of the starch solution by cutting the starch chains into oligosaccharides consisting of seven to ten glucose molecules. This is the so-called liquefaction step. Already in the mixing step during the mash preparation, the liquefying enzymes (alpha-amylase) need to be added to avoid problems due to gelatinization of the starch granules. The resulting mixture is heated and held at this temperature for a certain time. The pH also has to be adjusted according to the needs of the enzymes used.

The temperature ranges for the gelatinization of several cereals are well known (Ingeledew 2009). Depending on the type of cereal and the process strategy, the temperature can be held first below the gelatinization temperature which is usually in the range of 50–60°C for approximately 20 min and then heated up to the final liquefaction temperature which can be in the range of 80–85°C or even up to 105°C depending on the stability of the enzymes used. In another process strategy, the whole mash is heated up quickly to temperatures between 105°C and 120°C in a hydrotreater (jet cooker) unit. Here the temperature is held for approximately 5 min, then the whole mixture is fed to an atmospheric or vacuum flash vessel and from that to the liquefaction vessels where the enzymes are added. Within this process step, the temperature is held at around 80–90°C for about 30–60 min. The pH value can vary between 5.0 and 6.0 or 6.2 and 7.5 depending on the type of enzymes used [7].

If water is present during heating, the starch granules are dissolved which allows the enzymes to break the starch chains fast into smaller parts. This allows avoiding a very strong increase of viscosity and a blocking of the used equipment.

Bioethanol from Starch. Figure 2

Schematic layout of a dry-mill bioethanol process including distillers' dried grain with solubles (DDGS) production

After this liquefaction procedure, the whole mixture is cooled and the saccharification step is performed prior the start of the fermentation.

Saccharification Process As described above in the liquefaction step, the alpha-amylase can only break the 1,4-alpha glycosidic bonds of the starch. The second

enzymatic process step is needed to break down the dextrins into single glucose molecules by beta-amylase and glucoamylase. The latter is an exoenzyme which attacks the oligomers in the solution from the chain ends. Glucoamylase can hydrolyze 1,4-alpha glycosidic bonds as well as 1,6-alpha glycosidic bonds. But the reaction rate is much slower. The result is

a fermentable sugar solution containing glucose and maltose. The glucoamylase used in technical processes has a temperature optimum of 60°C and a pH optimum of 3.4–5.0. This means that this enzyme is stable under fermentation conditions. Due to this fact, it is possible to perform the saccharification in two ways.

- The first option is a separate saccharification vessel where the optimal temperature of the enzyme of 60°C can be adjusted and the fastest enzyme reaction rate can be achieved as it is shown in Fig. 1. This process strategy is also called separate hydrolysis and fermentation (SHF).
- The second option is that the saccharification step is combined with the fermentation to a simultaneous saccharification and fermentation (SSF) procedure. In this case, the temperature is around 33–34°C and the pH is approximately 5.0 resulting in an enzyme activity that is not as high as at the optimum. But since the yeast activity is the time-limiting step, the slow release of sugars is not limiting the process. This approach evermore shows the advantage that the optimal release speed of fermentable sugars keeps the yeast at the best performance rate, optimal temperature and pH assumed, since glucose itself is limiting the yeast at higher concentrations. This is the reason that in modern technical bioethanol plants the SSF approach is mainly used.

Yeast Propagation Before the fermentation process itself takes place, it is necessary to produce the yeast needed. Very often the yeast is grown in the bioethanol plant itself in smaller yeast-growing fermenter to be provided for the ethanol production fermenter. Some yeast can be recycled after ethanol production depending on the substrates used. Additionally, the solid matter content is restricting the yeast recycling. Working with clear streams like during processing of sugar solutions, a high degree of yeast recycle is possible after treatment. With starch as feedstock, yeast recycling is restricted.

The dominant yeast strain used in the ethanol production industry is *Saccharomyces cerevisiae* because it is a very robust organism which also shows a relative high inhibitor tolerance and a very good production capacity. Using this yeast, many plants in the USA

produce ethanol in the range of 20% (v/v) on volume basis which is equal to 16.5% (w/w) on weight basis [8].

Yeast shows the ability that only cell growth can be achieved in an aerobic environment in the presence of sufficient oxygen. Nearly no ethanol production occurs in this situation. This can be used for reproduction and increasing the cell mass as needed.

The commercial yeast production can start from active dry yeast supplied to ethanol production facility by specialized yeast-producing companies. Growing the yeast on site in a separate propagation vessel, it is possible to keep about 10% of concentrated yeast solution to start the next yeast production cycle. To continue this production cycle, it is very important that no bacterial infection occurs which has to be checked thoroughly. For the yeast propagation facility, sterile conditions are crucial. The same substrate as used for the ethanol production can be used for yeast propagation. In this case, the produced yeast is already adapted to the substrate. Only a dilution by a factor of 2 is used to keep the sugar concentration low and this also restricts the production of ethanol during yeast growth. The temperature is kept several degrees lower than during the ethanol fermentation and the propagation vessel is aerated to a sufficient amount avoiding the buildup of excessive foam.

The yeast propagation can be performed in a semicontinuous or in a continuous mode. The method chosen depends also on the performance mode of the ethanol fermentation itself.

Fermentation Process As the starch content in the feedstock cannot be directly converted by yeast cells to bioethanol, it needs to be broken down as described above into usable sugars before fermentation. These sugars can be the glucose itself or the maltose or maltotriose which consist of two or three glucose molecules. The different sugars which can be converted by the yeast *S. cerevisiae* are well known [2]. The resulting sugar solution is called mash. It can be used for fermentation which is started by adding the yeast inoculum.

During the fermentation, one glucose molecule is converted to two molecules of ethanol and two molecules of carbon dioxide. This means that in the ideal case from 1 kg Glucose, 0.511 kg ethanol and 0.489 kg

CO₂ are produced by yeast releasing 867 kJ heat [7]. The fermentation itself can be done in batch or continuous mode. Both systems have advantages and disadvantages.

- The batch fermentation mode is characterized by a discontinuous operation. First the fermentation vessel is cleaned and sterilized and then filled with the already liquefied mash after passing a heat exchanger to adjust it to the proper fermentation temperature below 35°C. Then the fermentation can be started by adding the already prepared yeast solution from the propagation vessel. The pH is adjusted to around 5.2 and kept constant by dosing a basic solution or allowed to decrease during the fermentation till a pH of 4.2. If the pH drops to a value lower than 4.0, most probably an infection with lactobacilli has occurred. During the fermentation period normally in the range of 50–60 h, the temperature has to be kept below 35°C by applying continuous cooling of the fermentation vessel. After finishing the fermentation, the alcoholic mash is pumped to a storage tank (called beer well). Then the cycle can be started again with cleaning and sterilization. Due to this procedure of emptying, cleaning, sterilization, and again filling of the fermentation vessel the effective time is reduced by around 20%. This means only 80% of the reactor volume is active. Therefore, a bigger reactor volume is needed. But since the whole plant requires a low degree on control equipment, low investment costs are resulting [2]. But high yields in the range of 90–95% of the theoretical yield combined with high ethanol concentration can be achieved. The size of the fermentation vessels are in the range of 800–1,500 m³. In Brazil in new plants, the volume of the fermentation vessels is increased up to 3,000 m³ [9].
- In the continuous fermentation mode, a constant stream of mash is fed to the first fermentation vessel. Depending on the feed volume stream and the vessel volume which is also in the range as mentioned above a certain residence time of the mash combined with a defined specific dilution rate is applied. It is very important that the specific dilution rate is below the growth rate of the yeast to keep the microorganism in the fermentation

vessel in the desired concentration range. Along the various fermentation vessels, the sugar is consumed by the yeast and ethanol and new yeast cells are produced during the fermentation. During this process the relevant parameters need to be measured and controlled properly. Additionally, a defined dosage of air is necessary to achieve a high specific production rate of ethanol of around 6 kg/m³ h. This is about more than three times higher as in batch systems with approximately 2 kg/m³ h. However, in the last fermentation vessels the yeast is already under stress due to high ethanol concentration so that cell recycling or fresh yeast addition might be required. In this case productivities of up to 30–50 kg/m³ h are possible [2]. The increased ethanol productivity of the continuous fermentation leads to a smaller fermentation volume. And the continuous process needs less manpower. The ethanol yield is with 89–93% slightly lower than in batch fermentation. Further restrictions are the rather uniform raw material quality needs. Continuous sterilization of the medium is needed to avoid contamination. Nevertheless, the risk of contamination is higher than in batch fermentation due to long time performance.

In industry, both fermentation systems are in use for starch-based ethanol plants in Europe. For example, a continuous fermentation process is used in Zeitz in Germany and a batch fermentation process is implemented within a plant in Galicia in Spain. In Brazil, approximately 75% of all existing ethanol plants use the batch fermentation process. The main reasons for that are higher production stability and lower risk of contamination [9].

Distillation and Rectification The main target of the fermentation is to convert nearly all sugar into ethanol. The next step within the overall process is the recovery of ethanol from the fermentation mixture (beer). This is done by applying a combination of distillation and rectification columns. A simplified scheme with the two columns can be seen in Fig. 2.

To separate the ethanol from water the whole fermentation broth has to be heated up until the boiling point of this mixture is reached. The boiling point of pure water is 100°C compared to 78.33°C of pure

ethanol [10]. The actual boiling point of the mixture depends on ethanol concentration [7] and comes closer to the ethanol boiling point with increasing ethanol concentration.

The evaporation takes place according to their vapor liquid equilibrium which leads to a higher concentration of ethanol in the vapor. Unfortunately, the ethanol–water mixture is not an ideal system and shows a so-called azeotrope with a minimum boiling temperature of 78.15°C. The azeotrope is a point where the concentration of the liquid phase is the same as the vapor phase. The ethanol water azeotrope is at around 96.5% (v/v) according to 95.57% (w/w). This concentration is the limit for the rectification process. Therefore, an additional separation process for dehydration of ethanol is needed (see entry “Dehydration of Ethanol”).

Depending on the ethanol concentration in the fermentation mixture which is in the range of 12–20% (v/v) (corresponding to approximately 10–16.5% [w/w]) it can be seen in Fig. 3 that the energy needed to concentrate ethanol to 94% (w/w) is around 2–3 MJ/l. This energy demand is nearly constant for this concentration range. To reach these values, an optimization and energy integration of the whole downstream processes needs to be applied.

It is very important, especially in the stripping section of the first column where the whole fermentation broth is feed in, that precautions are made to avoid the blocking of the column internals with the solid matter of the mixture. Therefore, very open tray constructions are used which can cope with this kind of mixtures. Concentration of the derived vapor phase in the rectifying part of the following columns is like in any other ethanol processing plant and dominated by the vapor liquid behavior of the ethanol water mixture [7, 11].

Dehydration Around the globe, there is not a common standard for the fuel ethanol quality. The allowed maximum of the water content is 0.2–1.0% (v/v) and depends on the country in which the ethanol is sold [12]. For concentrating the ethanol from 94% (w/w) (nearly azeotropic mixture) to the required quality several options are possible. The first option is continuing with an azeotropic rectification process which needs two additional columns and a third component added to the mixture to change the vapor liquid behavior [13–15]. Alternatively, an adsorption process can be applied [16, 17]. Also a membrane processes called pervaporation or vapor permeation can be used [18–20].

Bioethanol from Starch. Figure 3

Energy requirement for concentrating ethanol from fermentation broth concentration to a rectification column top product with 94% (w/w)

In Brazil, still many plants use an azeotropic rectification process using monoethylene glycol for dehydration of ethanol. That technology has been developed more than 10 years ago especially for these plants in Brazil. Its advantages are lower investment costs and high robustness on the industrial scale [9]. In the USA and also in Europe, most of the ethanol plants apply the pressure swing adsorption process using molecular sieves for removing water from ethanol to reach the necessary fuel grade. The molecular sieve is a special designed hydrophilic zeolite with a pore diameter of about 0.3–0.4 nm. This allows only water with a molecular size of 0.28 nm to enter and ethanol with a molecular size of 0.44 nm is not able to enter the zeolite. For the technical process, at least two vessels filled with the zeolite are needed. One vessel is used for adsorbing the water from the ethanol vapor stream at around 1.7 bar [21]. The adsorption pressure applied depends on the design of the distillation and rectification system in which the column pressure is increased from the distillation to the rectification section due the energy optimization reasons. So that on the top of the rectifier column a vapor stream is received with respective pressure. In the second vessel at the same time the zeolite is regenerated applying vacuum and a small purge stream of already purified ethanol vapor. This purge stream removes the adsorbed water and after regeneration the cycle starts again. The purge stream with the increased water content from this desorption process is feed back to the rectification column (Fig. 2).

After the dehydration process, the ethanol stream is ready for use and stored in a tank. During the storage and handling one has to take care that due to the hygroscopic nature of the ethanol humidity is not allowed to come in contact with dehydrated ethanol.

Processing of Stillage The remaining liquid stream from the distillation column (beer column) after ethanol removal is called stillage. The maximum remaining ethanol concentration allowed is in the range of 0.02% (w/w). In some plants the untreated stillage is recycled up to around 25% to the liquefaction vessel.

The remaining stillage coming from the beer column contains solids like the yeast cells and also dissolved matter like salts and other nutrients. Usually a solid liquid separation is applied using a centrifuge or

a decanter. This treatment results in a thin stillage stream (with dissolved matter from the feedstock) and a wet cake (containing the solids with a dry matter of around 25–35%). Depending on the used feedstock, a high recycling rate of the thin stillage is possible. For example by using corn as feedstock, the possible recycling rate can be up to 75%. With wheat and triticale only 60% of recycling is possible [22].

The rest of the thin stillage is feed into a multistage evaporation system for further concentration. Using four or more integrated evaporation stages the steam requirement for evaporation can be reduced to 200 kg steam per ton of water evaporated. In the evaporation process a stream called syrup is produced. The evaporation condensate can be feed back to the mashing vessel to be used again and to reduce the fresh water consumption.

In the next step, the syrup is mixed with the wet cake and feed to the drying system. Here DDGS is produced. The drying procedure is, due to high heat of evaporation of water, very energy intensive. The mixture of syrup and wet cake is very viscous and very sticky. Therefore, it is rather difficult to treat. In addition, smell and dust emissions during processing have to be kept very low. As a drying technology, direct or indirect drying can be applied. The technical equipment is a rotary or drum dryer. For better handling the DDGS product is often pelletized (see [7, 23]).

The derived DDGS product is a protein-rich animal feed with a crude protein content of around 30% or more [24]. In Table 2, the estimated amount of DDGS produced for different feedstock can be found. Depending on the original used biomass some differences can be observed. In Table 3, an example is given for DDGS quality derived from ethanol fermentation with wheat and corn and a mixture of thereof as a feedstock [25].

DDGS as a product contributes to the economy of the process but also increases the energy needed for the ethanol and DDGS production approximately by a factor of 2. The results are higher energy costs needed for the process. This also has an effect on the environmental situation of the ethanol production itself.

Another possibility is to use DDGS as a source of energy within the ethanol plant. This could be of financial benefit if the costs for energy and the earning for DDGS do not match. Therefore, in many countries

Bioethanol from Starch. Table 3 Chemical characteristics of DDGS (% w/w DM) derived from corn, wheat/corn mixture, and wheat [25]

Value	Corn	Wheat/corn (4:1)	Wheat
Moisture	11.8	8.0	8.1
Crude protein	30.3	42.4	44.5
Nonprotein nitrogen	5.4	12.4	10.2
Crude fat	12.8	4.7	2.9
Ash	4.8	5.0	5.3
Acid detergent fiber	14.6	19.5	21.1
Neutral detergent fiber	31.2	30.6	30.3
Crude fiber	7.0	7.8	7.6

such projects are evaluated [26]. DDGS as a fuel could provide more energy than the ethanol plant itself needs since the energy content is rather high. This means that still some of the DDGS could be sold as animal food. The major drawback is that the very high nitrogen content leads to a very high NO_x concentration in the flue gas when the DDGS is used as a solid fuel. Additionally due to the high sodium and potassium concentration, the ash shows a rather low melting point. Therefore, the use of DDGS as a solid fuel is a less promising option.

Stillage can also be used as a feedstock for biogas plants [27]. The amount of stillage produced within an ethanol plant depends strongly on the size of the plant. Therefore, for large ethanol production facilities very huge biogas plants would be needed. Additionally, problems might occur concerning the direct usage of the digested residue in agriculture due to necessary transport or pumping cost. Further treatment using simple filtration or membrane filters would allow higher concentration and would lead to a reduced liquid volume for further handling.

The stillage contains different amount of organic dry matter depending on the feedstock used for ethanol production. Therefore, the possible biogas production might vary significantly. For example, it is possible to produce from corn stillage $0.347 \text{ m}_N^3/\text{kg oDM}$ and $0.380 \text{ m}_N^3/\text{kg oDM}$ from the wheat stillage [28]. A general layout of an ethanol biogas concept can be seen in Fig. 4.

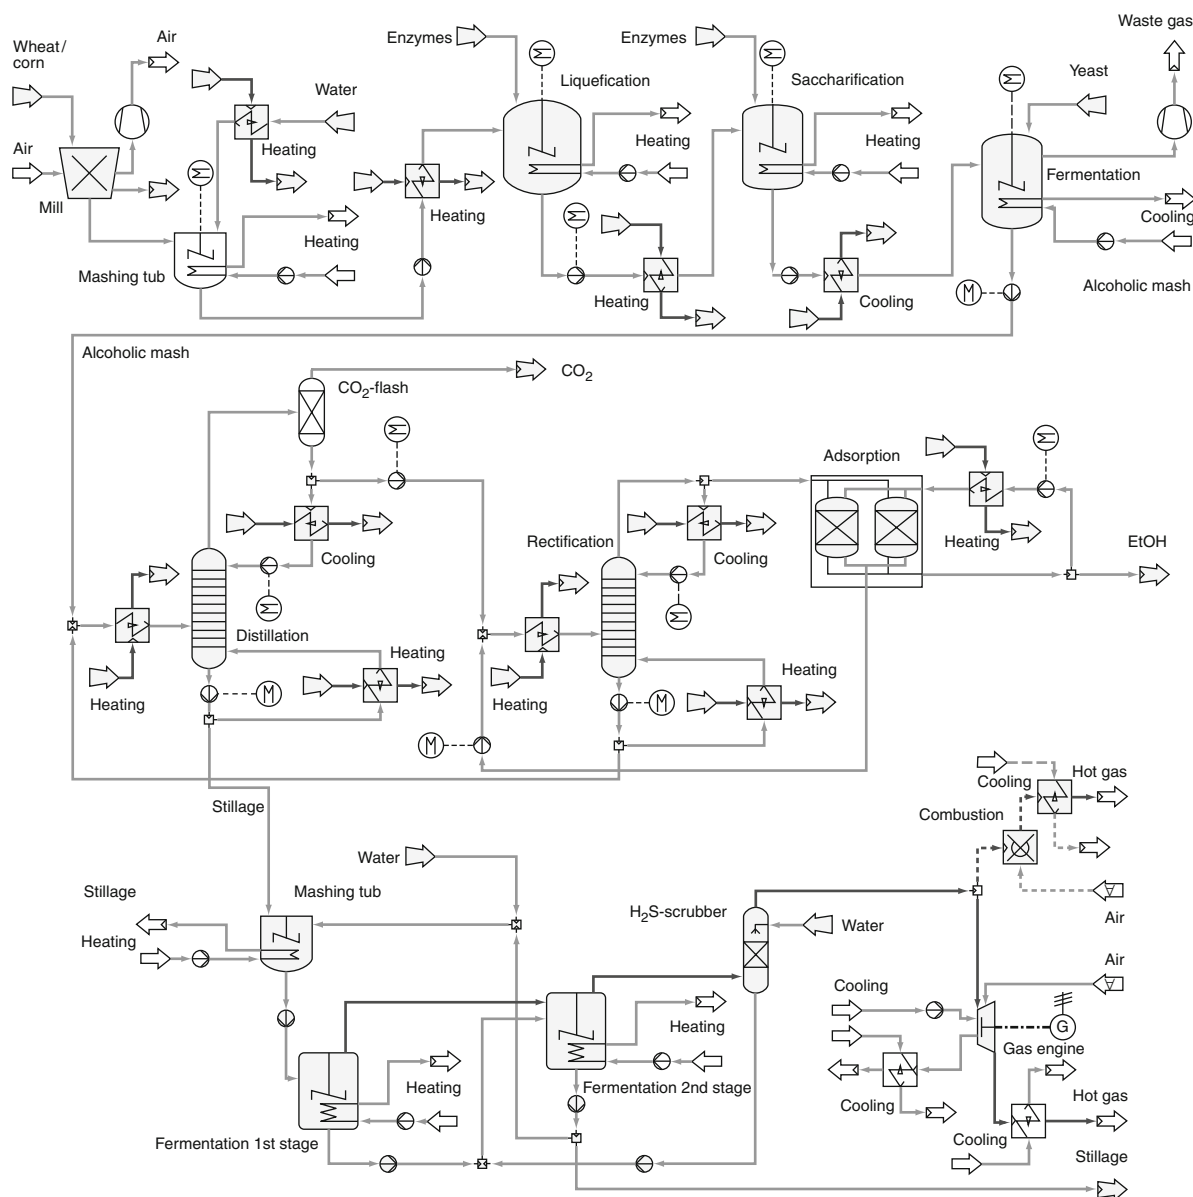

The biogas produced can be used in many different ways. It is possible to use it directly in a gas-fired boiler for steam production to cover the energy requirement of the ethanol plant as well as for electricity production (if the biogas production facility is big enough). Or it can be used for electricity production in a biogas-fired engine within a CHP process. Such process combinations together with optimized process integration can lead to a significant decrease of the energy demand of ethanol production [29].

Actual Status

A large-scale ethanol production has been realized within the USA for more than 30 years. The main source of feedstock used is grain. In Europe, the large-scale ethanol production as a fuel started in 2003, initiated by the European Parliament and the Council with posting the directive 2003/30/EC on the promotion of the use of biofuels or other renewable fuels for transport [30]. Since then many new ethanol plants have been built within EC-Countries to meet the requirements of replacing at least 5.75% of fossil fuel by biofuels based on the energy content by 2010. Single European countries enacted individual laws to follow the EC directive and in several countries even a tighter time schedule has been applied. For example, in Austria in 2004 a change in the existing fuel legislation [31] posted for October 1, 2005, a value of 2.5%, October 1, 2007, a value of 4.3%, and already on October 1, 2008, a fulfillment of the EC legislation of 5.75% based on the energy content.

The strong efforts of the USA and the EU in contributing significantly with biofuel to cover the energy demand within the transportation sector led to the situation that the USA passed Brazil as the world's largest annual ethanol producer in the year 2005 where both countries produced around 16 million cubic meters of ethanol. The world production in this year was 46 million cubic meters of ethanol. Since then the annual production capacities increased steadily worldwide to 74 million cubic meters ethanol in 2009 with 41 and 25 million cubic meters ethanol in the USA and Brazil respectively [32].

Analyzing these figures it can be estimated that around the year 2000 the ethanol production was 60% from biomass containing sugar and 40% from

Bioethanol from Starch. Figure 4

Schematic layout of a dry-mill ethanol process including Biogas production

grain crops (i.e., starch). Between 2000 and 2009 the situation changed to a ratio of approximately 40% from sugar crops and 60% from grain crops.

Following the trend of increasing production figures of ethanol, increasing amounts of starch crops are needed as a feedstock. The world production of grain crops in the period 2008/2009 was 2,231 million tons (without rice). This was around 5.2% above

the production of the year before 2007/2008 and has been the world's best production year ever. The prognoses for the year 2009/2010 are 2,196 million tons (without rice) which should be the second best production year ever. These record years in harvest are following after a deficit production in the year 2006/2007 which was followed by a very steep increase of price for the grain crops. A worldwide reaction was to

increase the land for grain crop production by 16 million hectares [33].

In the year 2008/2009, the worldwide harvest of corn was 791.9 million tons and that of wheat 682.8 million tons. In the European Community of 27 states (EC-27) the harvest of wheat was in the same year 315.2 million tons. For ethanol production, 5.0% of the wheat was used in the EC-27 in this period. Within the USA at the same period approximately 12% of the world corn production has been converted into ethanol [33].

Future Directions

After the rapid increase of large-quantity production of ethanol in a rather short time, it is important to continue on a settled basis to implement all experiences learned. This includes politics, environment, agriculture, and the ethanol process itself. The learning curve of the Brazilian and US ethanol industry over the last 30 years made it possible to reduce the production costs by more than 60% [34, 35]. This fact shows how important continuous process improvement is. For example, in the Brazilian ethanol industry it was possible to increase the fermentation yield from 75% to 92% based on the theoretical maximum during this time [9] which of course contributes significantly to the economics of the overall process. Actual production costs are estimated approximately with \$188/m³ in Brazil and \$310/m³ in the USA [35]. In Europe the estimated productions costs are around \$500/m³. Due the fact that Europe started large-scale ethanol production for the use as a fuel in 2003 [30] it can be expected that due to significant improvements the production costs of ethanol in Europe can be reduced in the future.

Further developments are already initiated from the European directive 2009 [36]. This regulation demands that on January 1, 2017, a 50% GHG saving target and on January 1, 2018, a 60% GHG reduction target have to be met. To reach these goals, the ethanol-producing industry is forced to improve the efficiency not only in the ethanol production process itself but also in the whole production chain to receive a better environmental performance.

This will influence the developments in all areas linked to the bioethanol production in industry and

research. The latter is urgently needed along the overall process chain to identify and exploit the given GHG reduction possibilities. On the agricultural side, crop developments are necessary to maximize starch production and lower pentosan and glucan concentration (responsible for high viscosity in the broth) with lowest environmental impact. Additionally, the existing substrate basis has to be extended. The use of various sugar, starch, and lignocellulosic material streams, or even mixtures will be needed to accomplish the given demands.

For the ethanol process itself, the optimization of the enzymatic steps and the fermentation process with high solid content is needed to provide together with optimized ethanol-producing microorganism high ethanol concentration at the end [37]. One route for optimization of the fermentation could be the removal of the remaining rough grain after dextrinization during the dry corn milling process. This would lead to an approximate 11% volume reduction of the fermentation vessels. Energy savings along the fermentation and distillation processes are the result since energy for cooling of the insoluble particles and heating in the distillation column is avoided.

At the moment, most of the dry grind fuel ethanol plants using the SSF process. Wet milling technology leads to solid-free mashes, which makes the yeast separation possible and water as well as yeast recycling can be done to a higher extent. The distillation will receive a solid-free stream which makes this step easier. The question is how the fermentation conditions (e.g., temperature, feeding of the carbon source) need to be set? This should be a mid-term program of further research activities because the question of the optimal balance between the fermentation time, the final alcohol concentration and yeast cell viability will strongly influence the economic situation of ethanol plants in the future [9].

In the downstream part, the process intensification with the help of membrane processes needs to be investigated. A first step in this direction is a large-scale pervaporation plant for ethanol dehydration from about 93% (w/w) to a quality of 99.5% (w/w) [20]. Further optimization would be possible if the inlet concentration of the energy-effective pervaporation plant could be reduced to 70% (w/w). This would result to a significant energy saving in the rectification

column. An energy-saving potential of 30–50% could be achieved [38]. The next step of optimization would be the application of an alternative process combination like stripping and membranes to perform ethanol separation from the fermentation broth itself. If a concentration of 70% (w/w) can be reached in the first process step this would close the gap between the second membrane separation steps for dehydration. This would avoid the energy-intensive distillation and rectification totally [39].

Furthermore, alternative usages for the stillage will be needed due to the large increase of worldwide DDGS production. This increase already significantly influences the whole fodder market. Expected limits of DDGS demands would result in falling prices. Since the stillage contains proteins, betaine, lipids, and organic acids and within the yeast cell most nitrogen is fixed in vitamins it might be possible to recover products with high selective and cost-efficient separation processes. The use of the stillage itself for the biogas production is from the environmental point of view a very interesting option. But it might be restricted to small- or middle-scale ethanol plants without effective separation process to increase the solid load of the biogas fermenter and to reduce the water demand significantly. This is also an important task for research. The suspected high nitrogen content in the liquid has to be taken into account. A main advantage of the biogas option is that the nitrogen is kept in the liquid phase, and is not lost as it is in DDGS incineration. This nitrogen can be used as a fertilizer in the agriculture which again improves the environmental performance due to reduced need of mineral fertilizer.

After all optimizations, a remaining demand of energy will be needed to drive all the processes along the ethanol production chain. For this energy needed, the optimal application of renewable energy will be important.

Glossary

Biofuel Biofuel is one type of bioenergy. In general, this term is used for liquid biofuels. The most known liquid biofuels are biodiesel and bioethanol.

Biofuel program In general, encompasses incentives to biofuels production and/or consumption through policies and regulatory frameworks.

Biomass Biomass is anything that has lived from vegetal or animal origin. The energy obtained from biomass (such as wood, straw, crops, etc.) to produce a fuel is known as bioenergy.

Energy balance Energy balance is the assessment of the energy content in a certain biofuel compared with the fossil fuel energy used to convert it.

Replication Repetition of an experiment utilizing key features. Following the Brazilian experience with ethanol, other countries have possibility to convert sugar plants into ethanol distilleries.

Sustainability Sustainability of biofuels production is related to environment protection, social welfare, and economic development.

Sustainable development Sustainable development is the utilization of the resources aiming to achieve better living conditions without disturbing the future generations' needs [1].

Tariff and non-tariff barriers Tariff barriers are duties imposed on tradable goods and services to be imported. Non-tariff barriers are a way to delimitate the trade by imposing conditions, quotas, and restrictions. Tariff and non-tariff barriers are barriers imposed mainly by developed countries against the import of products which may jeopardize local economy (or local farmers); they also occur in biofuels trade [2].

Definition and Importance of the Subject

The Brazilian ethanol program (Proalcool) is the oldest of such programs and started in 1975, producing ethanol from sugarcane. A similar program using corn was initiated around the year 2000.

The 2009 world's ethanol production was 76 billion liters – of which 41 billion is in the United States (USA) and 26 billion comes from Brazil – equivalent to 34.8 million tons of oil equivalent or 1.5% of total world oil consumption. The rest of it comes from different countries, mainly Europe and China. Ethanol production is increasing in several regions of the world: Of the 24 producing countries, there are 14 countries in Europe and 5 countries in Asia and Pacific area.

Since transportation is almost entirely dependent on petroleum products, liquid biofuels represent an option to address this challenge in the transportation sector, where there is no other renewable energy commercially available. It should be emphasized that 14% of the world greenhouse gases emissions come from transportation sector.

The main increased importance of biofuels is closely related to the current energy challenges, which are energy security, global warming, and the increasing energy needs of developing countries. This entry presents an overview of the Brazilian experience, lessons learned, and current policies to guarantee the production of biofuels in a sustainable way, as well as, perspectives for replicating it in other developing countries.

Introduction

From a technical perspective, there is nothing new in the renewed interest in using biofuels in internal combustion engines. Late in the nineteenth century, Henry Ford already used ethanol to drive automobiles and Rudolf Diesel used biodiesel from peanuts to drive trucks.

In the beginning of the twentieth century, these fuels were replaced by gasoline and diesel oil distilled from petroleum due to their higher affordability and availability in the USA and a few other countries with easy access to oil, while biofuels, particularly ethanol (an alcoholic beverage), were expensive and produced in minor quantities when compared to the huge quantities needed for large vehicle fleets.

In case of Brazil, since 1920, technical studies have been conducted in Brazil on ethanol-run vehicles, including racing cars. The reason for that was the good performance of ethanol used for fuel purposes, which made it a good alternative to imported gasoline. The first Brazilian policy supporting bioenergy was launched in 1931. The Brazilian Decree No. 19,717

required that all imported gasoline had to be blended with 5% of bioethanol from sugarcane. Later on, in 1938, this blend was extended to the gasoline produced in the country through the Law No. 737. The blend remained around 5.5% from 1935 to 1945 [3]. Over the years, the blend remained almost constant and slowly reached 7.5%. Such blend did not require any changes in the engines.

By the early 1970s, Brazil imported most of gasoline and petroleum consumed in the country, at an annual cost of US\$600 million. In 1973, with the first oil price shock, imports rose to more than US\$4 billion annually, contributing greatly to the deficit in hard currency and badly damaging the economy.

This was indeed a turning point, where the ethanol was no longer deemed as a by-product of sugar. In November of 1975, The National Ethanol Program, which is known as Proalcohol, was established. This program was the Federal government reaction to the “oil shock” and was created by the Decree No. 76,593. The program also served to assist sugar sector that was facing problems due to the low sugar price in the international market [4]. The production targets were set for 3 billion liters of ethanol by 1980 and 10.7 billion liters in 1985.

There were two distinct phases in the program. The first phase occurred from 1975 to 1979, emphasizing the production of anhydrous ethanol for gasoline blending as an additive to substitute MTBE (methyl tertiary-butyl ether), which is an ether added to gasoline to increase the octane by given oxygen to the combustion reaction. Once ethanol was added to gasoline, MTBE was eliminated as an additive. Ethanol has higher octane number than gasoline and performs the same role as MTBE without the presence of the toxic lead.

Other support actions to increase the competitiveness of ethanol were low interest loans for the construction of distilleries, guaranteed purchase of ethanol by the state-owned petroleum company (Petrobras), and subsidies. In this phase, gasoline was blended with 20% of ethanol and it was adopted a fixed price system, where 44 l of ethanol corresponded to 60 kg of sugar.

The time frame of the second phase spanned from 1980 to 1985, when the focus was on the production of hydrous ethanol for engines designed to run this fuel. The supply side was stimulated by diminishing the

parity of 60 kg of sugar to 38 l, and for the demand side, there were incentives among others over the fuel price and taxes reduction [5].

The background of the technological development of engines to run pure ethanol started in 1975 when the Federal Government learned about the research done by the Air Force Technological Center in São José dos Campos, São Paulo to develop ethanol-fueled cars using hydrated ethanol in a proportion of 95.5% pure ethanol to 4.5% water. Important changes in the engine were necessary in order to use that fuel.

One of those changes was the compression ratio that is 12:1 for ethanol fuel from sugarcane, while regular gasoline requires compression ratio of 8:1. Higher compression ratio signifies higher efficiency, which is partly compensated by the lower energy content in the ethanol. For the sake of the clarity, energy equivalence between the two fuels takes into account the final energy service provided. In this way, 199 l of pure (anhydrous) ethanol can replace one barrel of gasoline (159 l). The necessary changes in the engines to run ethanol meant a drastic change in automobile manufacturing, but under governmental pressure, local automobile manufacturers adjusted to that.

Sugar producers welcomed these changes that let them divert more sugarcane to ethanol production, and faced better oscillations in sugar prices in the international market. Another enthusiastic support came from nationalistic elements in the government, who saw ethanol as an instrument of national independence. One of the consequences was that driving Brazilian car with engine designed to run ethanol in neighboring countries (even some States of Brazil) was a problem because they did not have filling stations selling hydrated ethanol. The production of cars with pure ethanol engines began in 1978 with the participation of manufactures such as General Motors (Opel), Ford, Volkswagen and Fiat. Between 1979 and 1985, they accounted for 85% of all new car sales [6].

Over the same period, the percentage of ethanol in gasoline reached approximately 20%. The evolution of Brazilian ethanol production since beginning of the Proalcohol is illustrated in the Fig. 1.

Therefore, two types of automotive vehicles were present in the country: some running on gasoline, using a blend of up to 20% anhydrous ethanol and 80% gasoline, and others running entirely on hydrated

Bioethanol from Sugar: The Brazilian Experience. Figure 1
Evolution of ethanol production in Brazil [7]

ethanol. Nevertheless, it is important to mention that the targets were achieved through mandatory regulations, subsidies, and due to the unique characteristics of the country at that time, since Brazil was under an authoritarian government from 1964 to 1985.

In 1985, the scenario changed dramatically, as petroleum prices fell and sugar prices recovered on the international market. Subsidies were reduced and ethanol production could not keep up with demand. Therefore, by 1990, sales of cars running on pure ethanol dropped to 11.4% of the total [8].

The production of ethanol leveled off, but the total amount being used remained more or less the same because the decrease of hydrous ethanol cars was compensated by the increase on gasoline blending to 25% (Fig. 1). From 2003 onward, with the advent of flex fuel engines, ethanol consumption started to rise again. Since 2003, Brazilian automotive industry has introduced the so-called flex fuel vehicle, which means a vehicle running with any ethanol gasoline blend, from E-0 up to E-100. It must be noted that the Brazilian flex fuel vehicles are different from those produced in other countries (like USA), which can run with a maximum of 85% ethanol (E-85) only.

These cars are built to use pure ethanol with a high compression ratio (approximately 12:1); however, they can also run with any proportion of ethanol and gasoline, from zero to 100%. The increasing in the productivity of ethanol was reflected in costs (Fig. 2).

In 1980, ethanol cost roughly three times as much as gasoline in the international market (Fig. 2). And, since 2003, ethanol became fully competitive with gasoline without any subsidies. It is important to emphasize that this achievement is result of over 30 years of experience with technological gains, economies of scale, and political effort from policy makers and other stakeholders.

The expansion of ethanol production had important repercussions in the ownership and management of the sector, which in Brazil is entirely in the hands of private groups. Although Petrobras, the state-owned Brazilian oil company, is beginning to invest in this area, it is still a very small player [10].

Traditionally, sugar-producing units were family-owned enterprises such as Costa Pinho, São Martinho, and Santa Elisa, but new ones are owned by Brazilian companies including Votorantim, Vale, and Odebrecht. Also there are foreign companies entering the

Bioethanol from Sugar: The Brazilian Experience. Figure 2
Brazilian ethanol learning curve [9]

sugarcane business, including French (Tereos, Louis Dreyfus), Spanish (Abengoa), British (BP) and Japanese (Mitsui, Marubeni) groups, among others.

The financial sector is also quite active in this area, including Merrill Lynch, Soros, and Goldman Sachs. The presence of foreign investors has given the sector a new dynamism and new concepts of management.

Ethanol from Sugarcane

Sugarcane

Brazilian ethanol is produced from sugarcane (*Saccharum officinarum*), which is not an indigenous plant from Brazil.

In 1532, sugarcane was brought to Brazil by the Portuguese during the colonization period. This plant is a type of grass that has fibrous stalks containing high concentration of sugar. In order to achieve a good development, sugarcane needs distinct climate seasons. One phase is dedicated to germination, in which adequate rainfall and higher temperatures are necessary. During the phase for sucrose accumulation, it can be colder and dryer. The cultivation requires a minimum rainfall of 1,200–1,300 mm a year, in order to avoid

irrigation, and the ideal temperature ranges from 20°C to 24°C because this plant is not resistant to cold weather [10].

Brazil is a tropical country, and many of its regions have favorable climate characteristics for sugarcane cultivation without irrigation. Sugarcane is a semi-perennial crop, that is, after the planting phase, sugarcane can be harvested six to seven times without replanting; however, it is recommended one season of rotation with a different crop to rest the soil. This practice is common throughout the country.

Thus, in each harvesting season, 20% of the crop is replaced with crops that help to recover the soil such as beans, corn, or peanuts. The harvesting season follows the rainfall pattern of every region. As such, in the Center-South production region, it starts in April and finishes in December and in the North-East region, it spans from August to April. Depending on industrial process, sugarcane is transformed either in sugar or ethanol.

Sugarcane is the feedstock for alcohol (ethanol fuel, pharmacy or beverage), sugar, and electricity from bagasse as well. Vinasse (stillage), bagasse, filter cake, tops, and leaves (trash) are by-products from sugarcane that are also utilized in modern practices.

Bagasse (30% of the cane, 50% wet) is the remaining fibrous part of sugarcane after the crushing. It is rich in cellulose and contains more energy (560 Mcal/t of sugarcane) than ethanol itself (392 Mcal/t of sugarcane) [11]. This by-product is burned in boilers, providing heat and electricity.

Vinasse is generated from distillation. It consists of a liquid rich in organic matter and nutrients, such as potassium and calcium, but it is also a pollutant if not well managed. Vinasse production is around 10 l per liter of ethanol, but new technologies like vinasse concentration allows the reduction on the production of vinasse until 5 l for 1 l of ethanol (Magazoni LA, personal communication, magazoni@cerradinho.com.br). The use of vinasse in fertirrigation practice reduces the need for fertilizers and gives a no pollutant destination to this by-product. It must be noted that in the State of São Paulo, the use of vinasse for fertirrigation is controlled by the Environment Agency (CETESB) aiming to avoid contamination of underground water. This requirement will be probably followed by other States in Brazil.

Filter cake is also a by-product from juice filtration. It consists of rests of bagasse and sugar clarifier sludge, eliminating by 50% the need for phosphorus mineral fertilization. The production proportion for each ton of sugarcane milled varies from 30 to 40 kg of filter cake [11]. Tops and leaves (trash) represent 30% of the sugarcane. In many cases, they are the leftover of the harvesting and also left on the soil as preventive method avoiding erosion and nutrient depletion or utilized as cogeneration fuel.

From Field to Motor

Ethanol or ethyl alcohol is an organic compound that belongs to the first generation of biofuels (Box 1). Typically, ethanol is obtained through biological conversion involving fermentation process, which converts sugar into alcohol.

After the harvesting, sugarcane must be transported and processed in maximum of 72 h in order to avoid quality losses due to bacterial activity [12].

In the distillery, the grinding breaks the sugarcane fibers. Subsequently, acids or enzymes are added in

Box 1: Definitions of First- and Second-Generation Biofuels

First-Generation Biofuels The common forms of first-generation biofuels are those on the market in considerable quantities today. Typical first-generation biofuel is sugarcane ethanol, starch- or corn-based ethanol, biodiesel, biogas, and pure straight vegetable oil. The feedstock for producing first-generation biofuels are crops that produce sugars, starches, oils, or animal fats, most of them being food and feed, as well. It also can be obtained from residues. Other niche of biofuel is biogas, which results from an anaerobic treatment of manure, urban residues, and other biomass materials. Relatively small volumes of biogas are currently used for transportation. Today, the first-generation biofuels commercially produced is about 76 billion liters annually.

Second-Generation Biofuels Second-generation biofuels are those biofuels produced from cellulose, hemicellulose, or lignin. Examples of second-generation biofuels are cellulosic ethanol, Bio-SNG, and Fischer–Tropsch fuels. The latest technology synthesizes fuel from gases produced from the gasification of biomass. Both, first and second generation of biofuels can be blended with petroleum-based fuels, combusted in regular internal combustion engines, distributed through existing infrastructure. In addition, second generation may also be utilized in slightly adapted vehicles with internal combustion engines like vehicles designed to run Di-Methyl Ether (DME). According to Petrobras [17], the first bioethanol pilot plant has started activities utilizing enzymatic technology to convert waste into biofuels. Even though the second-generation biofuels are meant to be more sustainable, this technology needs technological breakthrough to reduce the production costs. Besides, second-generation biofuels are still in the development stage and production cost seems to be higher compared to first-generation ones.

Source: Reference [18].

order to precede the hydrolysis and obtain glucose. The glucose is then fermented to produce ethanol by the action of adequate yeasts.

Two important chemical characteristics of ethanol that should be emphasized are the boiling point (78.5°C) and the miscibility with water and organic components. There are two types of ethanol: The anhydrous form is used to blend gasoline and the hydrated one is used as fuel in engines specially designed for this type of fuel or flex fuel motor. The difference between the two types is the water content in the anhydrous and hydrated, which is 0.5% and 5%, respectively. Pure gasoline is called “gasoline A” and the gasoline blended with ethanol is “gasoline C” (gasohol). The percentage of ethanol blend in the “gasoline C” might range from 20% to 25%, according to the current legislation being regulated by The National Petroleum Agency (ANP). Among the ANP functions, supervision and control of the biofuel market is included.

Energy balance can be defined as the ratio of total fossil fuel energy required for the biofuel production process to the energy contained in the biofuel produced [13]. Energy balance of biofuel produced from a feedstock might be an indicator of the sustainability when taking into account greenhouse gas emissions avoided in a life cycle basis. A study on sugarcane ethanol energy balance shows significant differences between feedstock, where the energy balance of the

ethanol produced from sugarcane is 8.9, from sugar beet 2, and from corn 1.3 (Fig. 3) [14]. The sugarcane ethanol presents less GHG emission compared to fossil fuels due to the nearly closed carbon cycle. In respect of land use, feedstocks with higher yields per hectare require less quantity of land.

The good performance of the ethanol produced from sugarcane is due to the use of sugarcane bagasse that provides the energy needs for the process, eliminating external sources of energy. Bagasse is the most important by-product from sugarcane, and it is burned in the boiler producing both mechanical and electrical energy (i.e., cogeneration, see Sect. “Cogeneration in Sugarcane Mills”).

Another by-product that is increasingly growing in importance for energy generation to the process is the sugarcane leaves. This is happening due to the progressive decrease of the burning practice of sugarcane before harvesting and the progressive introduction of green cane harvesting.

Country Profile

Brazil is a large country and since the Proalcool program, it has always been an important player for ethanol production in the world. In order to give an idea of this country profile, the main social,

Bioethanol from Sugar: The Brazilian Experience. Figure 3
Energy balance from ethanol production from different feedstocks [14–16]

demographic, and economic indicators are summarized in the [Box 2](#), as well as, relevant information regarding production and use of ethanol.

Box 2: Brazil in Figures

The Federal Republic of Brazil has a continental size, 8,514,876 km². In 2008, the total population was 194,228 million inhabitants [19], and in 2007, the population growth was 1.2% [20]. Regarding economy, the Gross Domestic Product (GDP) corresponded to 2.4% of the world's GDP [20]; with 10% participation of agricultural sector [21]. Regarding the wealth distribution, in 2008, the Gini index was 57 [22]. The Human Development Index (HDI), which is a more complete index encompassing educational level, longevity, and income dimension, was 0.807. Yet, concerning HDI, in 2008, the country was positioned at the 70th place [23] in the world. Brazil is the second largest producer of ethanol in the world with 26 billion liters in 2009 [24]. This amount accounted for 37% of the world's production. This country is the world's largest sugar producer, with 622 million tons (metric tons) in the 2008/09 harvesting season [25]. In Brazil, the mills can be either a sugar plant or alcohol distillery or sugar mill and alcohol distillery. Most of the 414 existing Brazilian mills (60%) are alcohol distilleries attached to a sugar plant. In the period of 2008/2009, 35 new distilleries were to start production and another 43 were in different stages of development. In order to process quickly the feedstock, the sugarcane distilleries need to be close to the sugarcane plantation. The Center-South region responds for nearly 80% of ethanol production in the country. There is a high concentration of distilleries in the Center-South production region, but with no pressure against the Amazon or other important biomes in the country. Today Brazilians are driving about 24 million automobiles. In 2000, there were 2.8 million pure ethanol engine cars. Most of the pure ethanol cars have been retired while seven million of flex fuel cars are on the road and their numbers are increasing rapidly [26]. The huge success of these flex fuel vehicles is due to the freedom of choice for the consumers, depending on the price of each fuel at the gas station.

Sustainability Aspects of Sugarcane Ethanol

What are the issues regarding environmental, economic, and social aspects of the sustainability? Several studies [36, 65, 79] explored these issues deeply in recent papers summarized in this section.

Environmental zoning is a crucial tool to guarantee the sustainable production of sugarcane ethanol. There are such zonings in São Paulo State [27], in Minas Gerais State, and from the Federal Government. A recent environmental zoning for sugarcane (2009) from the Federal Government defined areas available for the crops and protecting biodiversity of important biomes named “Sugarcane agroecological zoning” a jointly effort from the Ministry of Agriculture and the Ministry of Environment. Besides that, there are studies [28] indicating that there is no scientific evidence that sugarcane crops present pressure on Amazon (Indirect Land Use Change – ILUC).

Environmental Aspects

In the beginning of the program, economic and strategic factors were crucial in reducing Brazil's dependence on oil, but later on, environmental preservation became also a key issue.

Ethanol engines present lower emissions than gasoline ones, such as no sulfur oxides or particulates, which are the primary cause of poor air quality in large cities like Beijing, Mexico City, São Paulo, and Los Angeles. In São Paulo, the air quality has improved remarkably since gasoline was partially replaced by ethanol. Nowadays, it represents more than 50% of the fuel powering vehicles.

Acknowledging that the main contributor to global climate changing is CO₂ from fossil fuel energy, ethanol has lower CO₂ emissions than gasoline because of the lower amount of CO₂ from fossil fuel energy produced over the ethanol life cycle. An important result was the approval from United States Environmental Protection Agency (EPA) [29] of the use of sugarcane ethanol, accepting that overall carbon balance is highly positive [28].

Besides, many environmental problems associated with oil production (spills), transportation (leakages), and consumption (emission of greenhouse gases (CO₂,

CH₄, N₂O), SO_x, NO_x, H₂O vapor and acid gases like HCl) are not present when using ethanol.

Therefore, below a brief overview of environmental impacts is presented, together with existing legislation to control them.

Water in Sugarcane Ethanol Production One of the most important issues related to water pollution in sugarcane industry was the adequate disposal of vinasse. Vinasse is a black liquid derived from distillation and fermentation, as already mentioned; this by-product is rich in organic matter with an acidic pH [4, 5]. It is a potential pollutant to water and can therefore not be discharged directly on rivers.

In the beginning of the program, there was no control on vinasse disposal from the mills and, in most cases, it was disposed in rivers, being responsible for high pollutant impacts. The solution to dispose this by-product was found, and it started to be recycled and used for fertirrigation. For some time, it was used for fertirrigation without any control. Therefore, the impacts related to the contamination of underground waters became important.

In 2006, in São Paulo State, the Environmental Agency (CETESB) started to control the amount of vinasse disposed on soils, aiming to avoid the contamination of underground water [30]. Nowadays, other states are also introducing the same control for the licensing of the mills.

Also there are now some initiatives aiming to reduce the amount of vinasse produced using systems for concentrating it (Magazoni LA, personal communication). By introducing such systems, the amount of vinasse produced decreased to 5 l per liter of ethanol produced.

Additionally, local environmental agencies all over the country are controlling the maintenance of riparian forests nearby sugarcane crops and requiring the reforestation of such areas with native forests, according the Federal Forest Code. In fact, it must be noted that this Code only states that it is forbidden to jeopardize the growing (or re-growing) of riparian forests. However, environmental agencies are requiring more than that: They consider mandatory the conservation (and/or reforestation) of these riparian forest of the plantations. This is an important issue, since it protects the quality of water in rivers.

Water is used in two ways in producing sugarcane and ethanol. Firstly, large quantities of water are needed to grow the cane. The cane requires significant rainfall, in the range of 1,500–2,500 mm a year, ideally spread uniformly across the growing cycle. Most of the sugarcane production in Brazil relies on rainfall, rather than irrigation, including nearly the entire São Paulo State sugarcane-producing region. Secondly, also large amounts of water are also used to convert sugarcane into ethanol. In 1997, this amount was calculated as cubic meters per ton of cane, from which 87% was used in four processes inside the plant.

In general lines, there is one process for sugarcane washing and three other industrial processes for ethanol production. Water consumption has substantially decreased in recent years. Furthermore, sugarcane is 70% water, which should provide enough for all the steps needed in ethanol production. There are distilleries being developed to be self-sufficient regarding water consumption. Also, nowadays the dry cleaning of sugarcane is being introduced in several mills, reducing the water consumption in the process (Magazoni LA, personal communication).

Land Availability Concerns related to the conservation of native forests and other important biomes are always presented and some studies even consider that any bioenergy crop comes from deforestation [31–33]. Notwithstanding, these studies only consider the worst case, which is not currently occurring, since biofuel production is not expanding into pristine tropical forests. If that did happen, of course, it would release a large amount of CO₂, but extensive studies have been conducted on the CO₂ releases resulting from other agricultural practices that do not involve deforestation, and the results are much less alarming [34]. Nevertheless, other studies [35] show that this is not adequate and bioenergy crops are being expanded in pasturelands without any deforestation.

In 2007, the land availability for agriculture in Brazil was 355 million hectares, from which 21% had already been used for agricultural purposes and the area occupied by sugarcane ethanol accounted only for 1.5% [7].

Moreover, there were 30% available land and 49% was occupied by pastureland. In this land, there is the possibility of expansion of agricultural crops, like has already occurred in the state of São Paulo through the

replacement of pastures, which have become more intensive [36].

In 2001, in the State of São Paulo, the average number of heads of cattle per hectare was 1.28. As of 2008, it has been increased to 1.56 because of the expanding sugarcane plantations pressuring cattle grazing. In the country as a whole, the density is even lower, at closer to one head per hectare [37].

The Brazilian sugarcane crops expansion is concentrated in the Center-South production region that does not encompass important biomes like Amazon Rain Forest, the Atlantic Forest, and the Pantanal [38]. The deforestation in the Amazon basin is linked closely with the raising of cattle for meat, for both domestic consumption and export; it is not linked with ethanol production. Today, Brazil has approximately 200 million heads of cattle on 237 million hectares [39]. In fact, if this cattle could grow in a more intensive way, reaching 1.5 heads for hectare (which is not yet an intensive growth), the country could have around 60 million hectares available.

In addition, recent studies [28] have analyzed Indirect Land Use Changes (ILUC), showing that there is no concrete evidence that sugarcane expansion is producing deforestation.

Soil Quality Sugarcane culture has become more sustainable over the years as some practices have been introduced insuring the appropriate use of fertilizers and soil protection against erosion, soil compaction, and moisture loss. In Brazil, some soils have been producing sugarcane for more than 200 years, with no yield reduction. In fact, agricultural production has increased significantly. Sugarcane culture in Brazil is well known for its relatively small loss of soil to erosion, especially when compared to soybeans and corn.

Nowadays, with the introduction of the green harvesting of sugarcane, a significant discussion is on the way, related to the amount of residues that should be left in the field to protect the soil. Studies show the importance of the sugarcane residues left in the soil, since they protect the soil and allow the infiltration of water in the soil and reduce erosion, among other benefits.

Agrochemicals Many inorganic compounds are introduced during the production of ethanol,

including chemicals that kill weeds, insects, mites, and fungi, along with defoliants and other chemicals that help the cane to mature more quickly. Concerning agrochemicals, fewer agrochemicals are used in sugarcane production than for some other crops. The pesticide consumption per hectare for sugarcane is lower than for citrus, corn, coffee, and soybeans. Nevertheless, sugarcane requires more herbicides per hectare than coffee.

Furthermore, comparing Brazil's major crops (those grown on areas larger than one million hectares), sugarcane uses smaller amounts of fertilizer than cotton, coffee, and oranges, and about the same amount as soybeans. Sugarcane also uses less fertilizer than sugarcane crops in other countries, for instance, compared to Australian sugarcane growers that use 48% more fertilizer than Brazilian ones [14].

One practice that helps here is using the vinasse as a fertilizer. This has led to a significant increase in productivity and in the potassium content of the soil [40]. Genetic research, especially the selection of resistant varieties, has made it possible to reduce the diseases affecting sugarcane, such as the mosaic virus, sugarcane smut and rust, and the sugarcane yellow leaf virus. With genetic modifications, plants are more resistant to herbicides, fungus, and the sugarcane beetle; some of these modifications are now being field tested.

Air Pollution Besides the advantages of sugarcane ethanol replacing gasoline in engines, with most of pollutant emissions being reduced, also emissions in sugarcane ethanol production must be addressed. In this area, there are two issues to be considered. Atmospheric emissions from sugarcane burning before harvesting and those from bagasse burned in boilers for cogeneration.

The sugarcane burning before harvesting practice was introduced in Brazilian sugarcane fields after the 1950s, aiming at higher productivity of the sugar cutter workers [40]. This practice eliminates the leaves of the sugar cane cleaning the way to proceed with the manual or mechanic harvesting. By doing this, up to 90% of undesirable vegetal matter can be removed from the harvesting feedstock [40]. Another reason for the burning is to avoid accidents with poisonous snakes and spiders.

However, there are serious drawbacks such as damaging the tissue of sugarcane and disturbing the soil structure enhancing the possibility of soil erosion [41]. Besides, there is an increase of pollutants such as particulate matter, carbon monoxide, and methane; locally it can increase the troposphere ozone concentration. Yet, there are several implications to the industrial phase like difficulties in the purification, need for faster utilization of the feedstock due to the shorter period for exteriorization [40].

It is important to emphasize that elimination of the burning practice raises the energy balance of the sugarcane, which means more energy is produced. Even though the burning is a controlled fire in a delimited area with maximum duration of 10 min [12], it might represent risks to the grid cables, roads, and highway. On one hand, harvesting manually the green cane is possible, but the celluloid leaves can hurt if no protection equipment is used. On the other hand, sugarcane burning enhances the level of organic compounds, particulate matter, and methane.

Recently, environmental legislation enforces the phasing out of sugarcane burning in the State of São Paulo (State Law 11.241; see Fig. 4). Further on, the so-called Green Protocol was signed. This protocol is a voluntarily one, signed between the Government of São Paulo State, through its Environmental Secretariat and its Secretariat for the Agriculture, together with the Sugarcane Agroindustrial Sector of São Paulo State,

reducing the timetable for the elimination of the burning process. The Green Protocol anticipated the timetable for elimination of sugarcane burning in the state from 2021 to 2014, as well as, increased the percentage of green cane harvesting from 50% to 70% in 2010, for soils with slope until 12%. In the case of slopes that are higher than 12%, the elimination of sugarcane burning was anticipated from 2031 to 2017 and it also intends to increase the harvesting of green cane from 10% to 30% in 2010. In many other states, the local environmental agencies are also requiring the harvesting of green cane as one of the exigencies for the environmental licensing.

Therefore, in the State of São Paulo, in the crop season of 2008/09, 49% of the cane was harvested mechanically [42] (Fig. 4). It is important to remind that 80% of the sugarcane produced in Brazil is from the Center-South producing region where the State of São Paulo is located.

Regarding the burning of bagasse in boilers for cogeneration, despite the advantages of this process for the industrial productivity of sugarcane ethanol, there are pollutant emissions to be controlled. Even considering that there is no sulfur in biomass (i.e., no SO₂-emissions), emissions of particulate matter and NO_x must be controlled. There is also an adequate environmental legislation in the country to do so. Therefore, there are now limits for emissions (particulate matter and NO_x) from such equipment [43].

Evolution of mechanical harvesting in the state of São Paulo. (Law 11, 241/2002) [42]

Economic Aspects

In response to environment issues, marketing forces took place increasing the demand for biofuels. This is especially true when the oil price is high [44]. The producers as suppliers act in a market-oriented way following the demand and tending to seek for more productivity.

Sugarcane Ethanol Production Costs Analyzing the inputs that are part of the production costs of biofuels, it can be noted that fertilizers, feedstock, and energy consumption are important indicators. In the case of sugarcane ethanol, the feedstock (sugarcane) represents the highest share of the final production cost.

Considering the overall process, the ethanol price can be up to 70% of gasoline prices, ranging from US \$0.18 to 0.25 per liter. This is the lowest production cost of biofuels in the world.

An analysis of the investment costs for plant with processing capacity of two million tons of sugarcane a year shows that it would be necessary an initial investment of around US\$60 million, in 2005 prices [45]. Assuming the plant to be a regular mill, located in the Center-South of Brazil, the yield would be on average 79.39 l of anhydrous ethanol or 82.86 l of hydrous per ton of sugarcane. And one ton of sugarcane would cost US\$11.4. Without computing the interest for a plant with a lifetime of 25 years would result in a cost of US \$0.143 per liter of ethanol and an investment cost of about US\$ 0.017 per liter of ethanol produced.

The learning curve showed in Fig. 2 illustrates the competitiveness of Brazilian ethanol with gasoline in the international market. Other sugarcane producer countries have potential to implement biofuel program following the production costs reduction achieved by Brazilian experience with biofuels.

It is important to note that nowadays there are no subsidies paid in the country, only special tariffs for ethanol when compared to gasoline.

Brazilian Taxes Associated to Ethanol By the end of the 1990s, ethanol subsidies have been removed by the government and, since then, there is no price control from the government [2]. The deregulation of the ethanol market began during the Real Plan, in 1994, with the reduction of tax discount on Federal Excise

Tax on Industrialized Products (IPI) for new vehicles powered by ethanol and also reduction of price difference between gasoline and ethanol [46].

Nowadays, the only incentives in place are allocated in the acquisition of new vehicles on IPI and in the Tax on the Circulation of Goods (ICMS). Among the States, the lowest ICMS is in the State of São Paulo (12%) and highest is in the State of Pará (30%), the average being 24% [37]. Flex fuel vehicles or vehicles powered by ethanol have lower IPI (Federal Tax for Industrialized Products) than gasoline ones (Table 1).

Actually, a higher IPI levy on vehicles powered with fuels which have higher emissions of pollutants is a way

Bioethanol from Sugar: The Brazilian Experience.

Table 1 Taxes according to the fuel and vehicle type

Tax burden on new vehicles		
Type of vehicle	Federal tax IPI [47, 48]*	
Gasohol vehicles (running on gasoline – anhydrous ethanol blends)	7–25%	
Ethanol vehicles	7–18%	
Flex fuel vehicles (running on any blend of gasoline/alcohol)	7–18%	
Tax burden on fuels		
	ICMS** (range)	CIDE tax [12]***
Gasoline	25–31%	R\$ 501.10/m ³
Diesel oil	12–17%	R\$ 154.80/m ³
Natural gas	12%–	Zero
Hydrated ethanol	12–30%	R\$ 22.54/m ³
Anhydrous ethanol (levy on gasohol)	–	–

*IPI – Federal tax where the levy varies according to the engine that ranges from 1,000 to 3,000 cm³

**ICMS – State tax and is lower for ethanol. These taxes take into account the environmental benefits of alcohol. In the case of anhydrous ethanol (blended with gasoline), there is no state tax (ICMS); this tax is included in the final blend (gasohol). The tax varies according to the State

***CIDE (Contribution for Intervention in Economic Domain), a Federal tax established in 2002 for liquid/gaseous fuels. CIDE was created aiming to get funds for road conservation in the country and establishes differentiated values according to each fuel

of internalizing the costs of externalities caused by them. The structure of ethanol taxes burden can be described in a simplified way [12] as:

- At industry level, on the ethanol anhydrous and hydrated, the PIS/Cofins levy is 3.65%, on the revenue after the ethanol sales.
- Considering retailer, the so-called PIS/Cofins levy is 8.2% in the revenue from sales of ethanol hydrated by the retailer. In case of anhydrous ethanol, this fuel is blended with gasoline, thus the levy evenly to gasoline.
- In terms of State tax, the ICMS (Tax on the Circulation of Goods) is a state tax on industry and retailer and for ethanol, it ranges from 12% to 30%.

PIS and Cofins are concerned to social security, being PIS the acronym for Program for Social Integration contribution and Cofins the acronym for Contribution for the Financing of Social Security. Cofins is an additional contribution to finance social security based on the gross turnover of the company.

Social Aspects of Sugarcane Ethanol Production

Biofuels production generates significant social benefits for the developing countries, like economic growth and decrease of unemployment rate for people with low years of schooling in rural areas, through the creation of jobs in such areas.

Also the investment needed to create these jobs is much lower in biofuels sector than in others. In Brazil,

one job position creation in ethanol agro industry costs about US\$11,000 and for petrochemical industry the cost is 20 times more [49]. Figure 5 shows capital investment for job creation in different production areas and the quantity of job per unit of energy produced.

Another important aspect of social situation in sugarcane sector is related to the quality of jobs created. The evolution of the poor people income share of participation on GDP is shown in Table 2. There, not only an increase of this participation can be seen, but also an increase in the number of poor people.

The social inequality of rural areas in Brazil has not been improving significantly in the recent years. This fact is confirmed by the Gini index shown in the Table 3.

Normally, the agricultural sector presents many informal jobs, that is, the worker is not included in the national social security system. However, regions with sugarcane production in general present better social situation.

In 1992, the formal employment exhibited a rate of 53.6% that improved to 72.9% now. Taking into account the regional differences in the country, it can be seen that, in the State of São Paulo, formal employment rate in the sugarcane industry is 93.8%, whereas in the North/Northeast region, it is only 60.8%.

Regarding wages, in the Center-South production region, people working with sugarcane earn more than those working with coffee, citrus, and corn, but less

than those working with soybeans because this work is highly mechanized requiring more specialized workers. In the Northeast, people working in sugarcane crops earn more than those working in coffee, rice, banana, manioc (cassava), and corn crops, being their income approximately equivalent to the ones working in citrus, but lower than those ones working for soybeans. In fact, the enforcement of labor regulations in some regions of the country could indeed be improved, aiming to achieve the same situation already existing in several sugarcane regions.

Temporary migration of rural workers during the crop season occurs because the place where they come from does not offer many job opportunities. Usually, the profile of rural worker in the sugarcane crop is described as male, young (under 30 years old), with low level of education, and migrant from other region [51]. The labor journey of rural field workers according to the law is 8 h a day with a 1 h break for lunch. Considering rural workers in the sugarcane crop, in 2004, the number of workers was 493,162 and about 50% were seasonal workers [52]. Table 4 shows the educational level of several workers categories in the

sugarcane production in the State of São Paulo. This table shows that the category holding the lowest educational level is the rural field workers (sugarcane cutters).

Manual Harvesting of Sugarcane Crops Manual harvesting of sugarcane is an old practice in every country producing sugarcane and the main problem is the working conditions. In order to facilitate the work and prevent accidents with poisonous spiders and snakes, it is a regular procedure to burn the leaves of sugarcane. Usually, sugarcane harvested manually occupies ten workers per hectare [53].

Considering the legislation related to work conditions, Brazilian Labor Law is strict with regulation, but there are exceptions. Thus, there is a need for more law enforcement, in order to reach welfare to all rural workers.

Regarding government social assistance to rural worker in Brazil, the latest social governmental program is “Fome Zero” (Zero Hunger) including initiatives like “Bolsa Família” (Family Allowance), an aid to rural family ensuring minimum price for their crop, taxes reduction on basic nutrition items. These are government tools of redistribution [54]; other instruments that can be associated to the rural worker are the minimum wage and the national social security system.

Mechanization of Sugarcane Harvesting Mechanization of the agriculture is a process that has been taking place all over the world. Similarly to the industrial revolution, in the mid 18th Century, man work

Source: Reference [37].

was replaced by machines, and this trend is also observed in the agricultural sector in Brazil. The mechanization process is happening not only in sugarcane crops, but also in other agricultural cultures, as well as, in other countries [55].

Since the beginning, the mechanization process has not been uniformly developed in Brazil, exhibiting distinct levels of mechanization depending on the region and on the type of crop [56]. In this way, the mechanization process for some agricultural crops is deemed partial due to the fact that harvesting process continued to be manual; one example is sugarcane crops that require a number of workmen for harvesting tasks.

The mechanization of the planting phase process has already changed the work relation and contributed to deteriorate the rural work quality giving raise to seasonal job. After the introduction of the legislation for the mechanization of the sugarcane harvesting, the mills have been investing in capacity building for the

rural workers aiming to develop more skilled people able to manage the mechanical harvesting machines, quite sophisticated equipment with computerized systems.

Seasonal Work Despite ethanol from sugarcane, rural field workers' condition is a subject of criticism, particularly the seasonal work. This sector holds the second highest seasonality in the country of 5.35 [57]. There is argumentation that seasonal job was a tendency of the agriculture [58].

Another reason pointed out was the agricultural modernization policy that was not favorable to small producers, who were not prepared either to production competition or work in the urban centers becoming seasonal workers [59]. Sometimes it is argued [60, 61] that the Federal Law N 4.214 from 1963, creating the Statute of the Rural Worker that extended to rural workers the same rights of the urban ones, has sped up the mechanization process.

In the State of São Paulo, the legislation goes beyond mechanizable areas with the recent legislation, Law N 11.241, of 2002. In order to follow the requirements of the legislation, the producers rapidly embrace mechanical power, but the level of mechanization depends upon availability of capital for investment.

As Brazil is a big country with regional differences, it is possible that part of the harvesting will continue to be manual, for some time, following the legislation schedule.

The alternative of harvesting with machines might cause unemployment of rural workers with low level of education that, possibly, will have difficulties to fit in the labor market. Regarding the sugar cutter unemployment, the legislation intends to tackle this problem including qualification of rural workers involving the partnership of unions. According to UNICA [62], with the effort of the associated companies, it is possible to improve the skills (qualification) of 7,000 workers a year.

The State of the Art on Sugarcane Ethanol

In the last 30 years, many technological improvements happened in ethanol field in agricultural and industrial production, in logistics and in the end users [63]. To do so, it was necessary to give subsidies at the initial stage, initiate negotiation among the sectors involved, and pass specific legislation [64] to open a window of opportunities and attract investments.

This topic will describe the state of the art of the fleet compatibility with ethanol, cogeneration process, technological development achieved, and logistic.

Compatibility of the Existing Fleet with Ethanol

This topic reports technological issues related to compatibility of the fleet with ethanol. Starting with the effect of ethanol on regular gasoline engine fleets, it then describes technological aspects of ethanol engine fleets and finally the new flex fuel engines.

Generally, the use of ethanol raises concerns about the compatibility of the regular existing fleet, as well as, the higher fuel consumption, since ethanol has lower energy content than gasoline.

The consumption drawback is partly compensated by the higher compression ratio that gives higher

efficiency to the fuel. Regarding regular fleet compatibility, the concerns rely on drivability, cold start, and damages of components of the vehicle. The losses in drivability may arise due to different ratio air/fuel for the combustion while cold start difficulties are caused by the lower vapor pressure. Most of the worries are the chemical attack in plastic and rubber materials of vehicle and corrosion of metallic materials of vehicle. Notwithstanding, the occurrence of these events aforementioned depends upon the amount of ethanol blended with the gasoline, the vehicle age (reflecting its technological level), and the ethanol fuel specification and quality [45].

Furthermore, small blends of ethanol with gasoline up to 5% are acknowledged as inoffensive to the regular fleet. The World Wide Fuel Charter [65] establishes maximum oxygen content in gasoline of 2.7% m/m, that is, blends higher than 5% are allowed by this specification. Many countries have introduced low concentration of ethanol blended with gasoline (up to 10%) as regular fuel for vehicles developed for neat gasoline without significant performance loss. In case of vehicles with electronic fuel injection (EFI System), this device enables automatic correction of the engine air/fuel ratio. Ethanol blended with gasoline presents a relatively low consumption increase of less than 3%. Table 5 [66] displays the necessary adjustments in vehicles for the use of national sugarcane ethanol blends.

Cogeneration in Sugarcane Mills

Cogeneration process is the simultaneous electric/mechanical and thermal energy production from the same energy source. In the case of Brazilian sugar/ethanol mills, the source of energy is sugarcane bagasse.

Until the late 1990s, sugarcane bagasse was deemed an undesirable waste by the sector and was inefficiently burned or traded. Later on, the situation started to modify due to the need of changing the old boilers with 20 years in the edge of their life cycle. Some mills started to introduce more efficient boilers (higher-pressure boilers, up to 80 bar, instead of the old ones working with 21 bar) [4]. Step by step, other mills also became interested on this technology and the improvements started to happen.

Associated to this fact, another action that propelled the technological upgrade was the Program for

Bioethanol from Sugar: The Brazilian Experience. Table 5 Fleet adjustment to run ethanol

Ethanol content in the fuel	Carburetor	Fuel injection	Fuel pump	Fuel pressure	Fuel filter	Ignition system	Evaporative system	Fuel tank	Catalytic converter	Basic engine	Motor oil	Intake manifold	Exhaust system	Cold start system

Source: Reference [66].

Alternative Electric Generation Sources and Wind Energy (PROINFA) that was a political incentive to energy generated from renewable sources. In the case of biomass, where sugarcane bagasse cogeneration is included, the electricity surplus sold to the grid relies on several aspects, such as the type of cogeneration technology used, the quantity of steam consumed to produce sugar and/or ethanol, and the amount of bagasse available [64].

In 2007, the total electrical energy sold in the market was about 900 MW, and nowadays, it is 1,000 MW. The plants work in a complementary basis with the hydroelectric system, since the plants are operating at full power in the dry season in the Center-South. In fact, there are still several opportunities for enhancing the power generation if all the plants are modernized and the use of tops and leaves (trash) of the sugarcane is introduced with the mechanization of green cane.

PROINFA was created by the Law N 10438, 2002, that established that 3,000 MW would be purchased from renewable energy sources, specially wind, small hydro, and biomass. In the case of biomass, actually the price and long-term contracts (20 years), established for electricity purchase, were not considered attractive to make all the mills modernize to produce surplus of electricity. Therefore, the limit of 1,000 MW was not achieved by biomass and the share of power not bought from biomass was transferred to wind and small hydro sources of energy.

Actually, most mills prefer to send their electricity surplus to the utilities in short term contracts. Besides that, also the grid connection is still a barrier that needs to be overcome; by the time this entry was written, many mills were developing special agreements in order to allow the construction of transmission lines from the plant until the grid (see also [65]).

Technological Development

In Brazilian experience of producing ethanol, three technological phases can be identified [37]. In the first phase, from 1975 to 1985, the focus was on productivity to supply the growing demand. This phase was characterized by the search for higher milling capacity, improvements of distillation systems,

fermentation productivity gains, and agricultural productivity increase.

Since the production was stabilized, as of 1980, the emphases shifted to better conversion efficiency such as higher efficiency of the extraction and fermentation phase. In the mid-1980s, there was more attention in technological tools for agro-industrial production management like optimization and renovation of sugarcane plantations in order to monitor the harvest, control the operational processes, and control simultaneously agriculture and industry. The development was not homogeneous, and the three phases can still be found. Comparing the maximum conversion efficiency to the average values, 10% difference could be found between the production units, but growing over the time indicating large internal technology transfer.

The most relevant information about the technological development is summarized in Box 3. According to this, the Brazilian technological level for ethanol fuel production is deemed the best in the world (as proven by the production costs and the conversion efficiencies). In the sugarcane research area, Brazil shows the largest number of technical publications [64].

Box 3: Technological Development

Period of 1980–1990: Large-scale introduction of sugarcane varieties developed in Brazil (mainly by CTC-Copersucar and Planalsucar programs); development of the full use of the sugarcane stillage in fertirrigation; biological controls in sugarcane production; development of the milling system with four cylinders; power production in the industry (self-sufficiency); end use; ethanol specifications; ethanol engines, ethanol transportation, blending and storage.

Period of 1990–2000: Optimization in sugarcane cutting, loading and conveyance; sugarcane genome mapping; genetic transformations, harvesting mechanization, achievement of electric power supply and their selling to the grid; advancements in industrial automatization; enhancement in technological management (both industrial and agricultural); introduction of flex fuel engines.

Source: Reference [63].

Logistics

The production of biofuels requires the existence or development of a support structure to collect the biomass, transport it to the industrial plant to be processed, and to distribute the biofuel. This is an important issue when the perspective of replication the Brazilian experience is being discussed, as is happening nowadays.

In addition to the requirements mentioned above, there is also the need for appropriate facilities for storage. The logistical structure of biofuels is complex and involves local, regional, and long distance transportation, delivering the product to other consumer centers or even to export. Depending on market destination of the ethanol (internal or exportation), the logistic must be handled separately.

If the final destination is the internal market, the production must be delivered to a fuel distribution base because of legal reasons; however, if the production is going to be exported, the commercialization can be developed directly from production plant or fuel distribution base [67]. Regarding the storage facilities, the storage might be done either by the producer storing the production surplus in tanks inside the industry or by the retailer in the terminals to guarantee the supply in short term [41].

Brazil has a logistic structure consolidated and well distributed for hydrated ethanol or anhydrous ethanol blended with gasoline, where both types of ethanol hydrous and anhydrous are transported via road, rail, and pipelines [68].

At long term, the infrastructure of storage capacity does not seem to be a limiting factor. In 2007, there were 273 retailer spread around all the states of the country with storage capacity of 3.75 million cubic meters [41]. Unlikely the storage, the infrastructure of ethanol transportation regarding the growing production seems to be a bottleneck for developing countries with a lack of local infrastructure.

International Dimensions of the Ethanol Program

Ethanol Programs in Other Countries

Several countries have already started biofuel programs. The most important one existing today (and also the largest one) is the US ethanol program,

producing ethanol from corn. The current production of corn ethanol by the USA reaches 41 billion liters [69].

The 2007 US Energy Bill set a target of producing 15 billion gallons (56.8 billion liters) of ethanol a year from corn by 2015, using first-generation technologies, which will probably require an agricultural area of approximately 14 million hectares. Further expansion of production is planned, up to 21 billion gallons (79.5 billion liters) a year, using cellulosic materials and second-generation technologies that are still in experimental phase.

Another policy pointing in this direction is the European Union directive, which will require 3.9 billion gallons per year by 2020 in order to replace 10% of the gasoline for internal consumption. At the present, their production is two billion liters a year. Production of ethanol from corn, using first-generation technologies, will be at least 87.8 billion liters a year in 2015, up from 36.8 billion in 2006.

There is an important difference between the production of ethanol from sugarcane in Brazil or from corn in the USA, and from starch feedstock in Europe. The difference between them relies on industrial processes that require external sources of energy like oil or gas to supply electricity and heat.

In practical terms, in USA and European Union (E.U.), ethanol is obtained partly by burning coal (the main source of energy in the region) to produce the energy necessary to the processes inside the distilleries. Unlike USA and E.U., in Brazil, the use of sugarcane bagasse as feedstock makes far better energy usage avoiding fossil fuel consumption. This is possible due to energy content in the feedstock. The concept of energy balance used to evaluate the use of fossil fuels in preparing ethanol was already discussed in the Sect. “From Field to Motor”.

Many studies have been conducted on this subject, and the results are sensitive to assumptions about the use of fertilizers, pesticides, and other energy inputs. According to one estimation compared to gasoline, ethanol from corn emits 30% less CO₂ and ethanol from sugarcane 82% less [70].

In the USA, efforts to expand ethanol production from corn face severe obstacles. The amount of corn directed to ethanol production is already 18% of the production, spread in a total area of 37 million

hectares. The increase in corn-planted area has been made at the expense of soybean-planted area. Production of ethanol from cellulosic materials, which could be a solution, is still facing technological problems that are not likely to be solved by 2015. Nevertheless, productivity increases including genetic modification might represent a significant reduction in the amount of additional land necessary.

This large demand for ethanol and the corresponding use of agricultural land to produce it have generated a number of objections to the use of biofuels. Some argue that the competition between land for fuel (ethanol) and land for food, in both the USA and Europe, is causing famine around the world and leading indirectly to deforestation in the Amazon and other tropical areas [31, 32]. The recent rise in the prices of agricultural products, after several decades of declining real prices, is often seen as a cause of famine, and led to the politically laden debate of fuel versus food. All together, the grain prices have more than doubled since January 2006, with over 60% of the rise happening since January 2008. It was closely following the price of petroleum that started to diminish when 2008 crop was harvested. In contrast, the point has been made that higher crop prices will not necessarily harm the poorest people because many of the world's 800 million undernourished people are farmers or farm labors, who could benefit from higher prices.

More recently, the price of agricultural products has decreased following the decline in petroleum prices. To keep the issue in perspective, it is important to remember several facts. First, around the world, 93 million hectares are currently being used to grow soybeans and 148 million hectares for corn, while the amount used in the USA to produce ethanol is approximately seven million hectares. Second, in general, the prices of food commodities have been decreasing since 1975, but fluctuations frequently occur in those prices, as well as, in the areas planted and the prices of crude oil. Those fluctuations, which have occurred for decades, result from many factors and events [64] and not due to biofuels expansion.

Worldwide, 1.5 billion hectares of the arable land is already being used for agriculture and another 440 million hectares is potentially available, including 250 million hectares in Latin America and 180 million in Africa. As such, the area currently being used for

biofuels is only 0.55% of the land in use. This expansion has been extensively analyzed in many reports (e.g., [34]) which pointed out that several individual factors have driven up grain prices and in combination led to an upward price spiral. Among them are high energy and fertilizer prices, the continuing depreciation of the US dollar, drought in Australia, growing global demand for grains (particularly in China), changes in some nations' import-export policies, speculative activity on future commodities trading, and regional problems driven by subsidies of biofuel production in the USA and E.U.

One example is the land changes in the USA in the period 2006–2007, corn acreage grew 19% utilizing nearly 37 million hectares, an increase of 7 million hectares. Most of this expansion came at the expense of soybean acreage, which decreased by 17%, from 31 to 26 million hectares (i.e., 5 million hectares). This is approximately 6% of the world's area used for that crop, and that change is helping to drive up prices.

Because of this land changes, other countries had to expand their soybean production, possibly increasing deforestation in Amazon. Such speculations about a *domino effect* are not borne out by the facts since the area used for soybeans in Brazil (mainly in Amazon) has not increased from 2004 onward. The deforestation in the Amazon rain forest has been going on for a long time at a rate of approximately one million hectares per year [71], and recent increases are not due to soybean expansion but due to cattle and are inconsistently related to ethanol production [35].

Replicating the Brazilian Experience Elsewhere

Almost 100 countries are producing sugarcane over an area of 20 million hectares and the fifteen most important producers hold 86% of the sugarcane production. And the conversion of sugar plants into ethanol distilleries is relatively easy, and most of the existing plants in Brazil have these dual purposes. Taking advantage of the easy reversibility of the production units, the ethanol production in other countries could be significantly expanded following the Brazilian experience with ethanol, using a fraction of their sugarcane for ethanol.

The question that arises is: Why are other sugarcane-producing countries not using some of their raw material to produce ethanol? One, it could be export to the

Bioethanol from Sugar: The Brazilian Experience.**Table 6** Subsidies for biofuels in the USA and E.U., 2006

	Ethanol			Biodiesel		
	Total, in US\$ billions	Billions of liters	US \$/l	Total, in US\$ billions	Billions of liters	US \$/l
US	5.8	20.7	0.28	0.53	0.96	0.55

USA and E.U., where production costs are significantly higher. The main reason is the high import duties imposed on ethanol imports in the USA and E.U. to protect local industries, which are heavily subsidized. Table 6 displays an estimation of the subsidies in the USA and E.U., which totaled almost \$12 billion in 2006.

Removing these subsidies is a topic of discussion in the Doha round of negotiations, but prospects for progress in this area are poor (Box 4). Several countries in Central America benefit from their privileged access to the US market. The members of the Caribbean Basin Initiative (CBI), the oldest group, up to 7% of the previous year's US ethanol demand is exempt from import tariffs [2, 73].

This agreement has been used mostly to allow these countries to import dehydrated Brazilian ethanol. In the past, European hydrous ethanol was also included. Dehydration plants are located in Costa Rica, the Dominican Republic, Trinidad and Tobago, El Salvador and Jamaica. The USA imported 482 million liters from these countries in 2006 and 877 million liters in 2007, considerably less than the 1.3 billion liters that the 7% limit represents on ethanol imported from Caribbean countries. The Central America Free Trade Agreement (CAFTA), signed in August 2004, immediately eliminated all tariffs and quantitative restrictions on 80% of manufactured goods in that market, including ethanol, with the remainder phased out over a few years. Nearly all of the 6 nations in CAFTA have already initiated plans to develop large-scale ethanol production. El Salvador is the most advanced, since it has already

Box 4: Biofuels and the World Trade Organization

Nowadays, the World Trade Organization (WTO) does not have a specific trade regime for biofuels. Therefore, international trade in biofuels falls under the rules of the General Agreement on Tariffs and Trade (GATT, 1994), which covers trade in all goods, as well as, other relevant WTO agreements such as those on agriculture, technical barriers to trade, the application of sanitary and phytosanitary measures, and subsidies and countervailing measures. Agricultural products are subject to GATT and to the general rules of the WTO, insofar the Agreement on Agriculture (AoA) does not contain derogating provisions. Key trade-related issues include the classification for tariff purposes of biofuel products as agriculture, industrial, or environmental goods; the role of subsidies in increasing production; and the degree of consistency among various domestic measures and WTO standards. The AoA covers products from Chaps. 1 to 24 of the Harmonized System, with the exception of fish and fish products and the addition of many specific products, including hides and skins, silk, wool, cotton, flax, and modified starches. The discipline of the AoA is based on three pillars: market access, domestic subsidies, and export subsidies. One of its main features is that it allows members to pay subsidies in derogation from the Agreement on Subsidies and Countervailing Measures. The Harmonized System classification affects the way products are characterized under specific WTO agreements. In this classification, ethanol is deemed as an agricultural product being subject to Annex 1 of the AoA, whereas biodiesel is classified as an industrial product and is therefore not subject to the disciplines of the AoA. The paragraph 3 (iii) of the Doha Development Agenda displays negotiations on "the reduction or, as appropriate, elimination of tariff and non-tariff barriers to environmental goods and services." Some WTO members have suggested that renewable energy products, including ethanol and biodiesel, should be classified as "environmental goods" and therefore subject to negotiations under the "Environmental Goods and Services" cluster.

Sources: References [76–78].

drafted legislation to continue developing a local ethanol market and is beginning to invest in ethanol production. An old distillery that can produce 60 million liters a year is being revamped to double its capacity and is already exporting all its production. Similar initiatives are underway in Guatemala and Costa Rica [74].

Across the Atlantic, two key elements of the E.U. General System of Preferences are the *Everything but Arms* (EBA) initiative and the *Special Incentive Arrangement for Sustainable Development and Good Governance* (GSP+). EBA provides special treatment for fifty least-developed countries, giving duty-free access to imports of all products except arms and ammunition, without any restrictions on quantity, with the exception of rice and sugar up to October 2009. At present, GSP+ benefits 16 countries, mostly in Latin America and the Caribbean. Any GSP+ beneficiary country must be both “vulnerable,” according to a definition established in the regulation, and have ratified and effectively implemented 27 specified international conventions in the fields of human rights, core labor standards, sustainable development, and good governance. This program grants special duty-free access to the E.U. market for denatured or non-denatured alcohol [75]. In order to benefit from such

advantages, a few countries in Latin America and Africa are starting to divert some of their sugarcane to ethanol production and others, especially Venezuela, are expanding their sugarcane plantations. Regarding these issues, some recent reports from UNCTAD discuss on only certification issues and the impact on developing countries, as well as, the perspectives for second-generation technologies in these countries [2]. Table 7 provides a list of projects underway around the world.

This development represents a modernization of the sector which traditionally was in the hands of prosperous family groups that benefited from special relationships with the E.U. that let them sell sugar at far more than the international price. Their price was based on the much higher price of locally produced sugar from sugar beets or sweet sorghum. This comfortable situation discouraged them from entering into the ethanol business, which required additional investments and know-how.

Future Directions

If second-generation technologies do not materialize until 2022, most of the ethanol required in the USA will probably have to be imported from countries in the Southern Hemisphere, such as Brazil where the sustainable land expansion and good climate particularly favor its production from sugarcane.

In all likelihood, ethanol consumption, which represented 0.4 million barrels of oil equivalent per day in 2006 (1.2% of all gasoline in use in the world) will grow to 2.6 million barrels of oil equivalent per day in 2022, replacing 10% of all gasoline used in the world. Considering that current oil consumption is 85 million barrels a day and that it might grow to 100 million by 2012, ethanol would be contributing the equivalent of almost 3% of the world's consumption of oil. That is a significant amount and will help drive down the world price of petroleum.

Neither USA nor E.U. will be able to produce all the ethanol it needs; in all likelihood, they will have to import it from Brazil and other tropical sugarcane-producing countries. This could be a mutually beneficial solution, reducing the cost of fuel for consumers in the USA and E.U. and generating hundreds of thousands of jobs in the developing countries.

Bioethanol from Sugar: The Brazilian Experience.

Glossary

Alcohol A compound in which the –OH group is connected to an aliphatic carbon atom.

Biofuel General classification of a fuel refined from recently harvested organic matter.

Biomass The solid form of biofuel.

Biogas The gaseous form of biofuel.

Bioliqid The liquid form of biofuel, ethanol, and biodiesel.

Catalyst A substance that enables a chemical reaction to proceed at a usually faster rate or under different conditions (as at a lower temperature) than otherwise possible.

Cetane number A measure of the ignition quality of diesel fuel and influences combustion characteristics.

Feedstock The raw material that will be processed into a fuel.

Petrol-diesel Diesel fuel that is derived from petroleum.

Pour point The temperature at which a liquid stops behaving like a liquid.

Transesterification The process of converting one ester into another ester using an alcohol and oil.

Definition of the Subject and Its Importance

Biofuels come in many forms and from a variety of sources. The biofuels may be solid (biomass), gas (biogas), or in liquid form (biodiesel, ethanol, etc.). Biofuels may be derived from most plant material as well as some animal parts, typically animal fats. As plants grow over much of the world's landmass and their primary source of energy is the sun, biofuels are abundant and renewable. Furthermore, as biofuels absorb the sun's energy to grow, biofuels are nature's solar energy battery.

Biofuels have been used for thousands of years as a source of heat and light for civilization. However, as humanity's energy consumption has become more sophisticated, fossil fuels have gained a technological edge in refining and supply chain management. For the last decade, renewed interest in biofuels has increased the adoption of biofuels for making heat and electricity. The drivers for the interest in biofuels are many; including energy security, environmental concerns, and economic competitiveness.

To address all these interests, the entire life cycle of the biofuel and its use must be considered. Energy security or establishing an effective/reliable supply of biofuels is a must for any building operator considering biofuels as a primary fuel source. Pollution concerns may drive a building operator toward or away from biofuels. For example, soy-based biodiesel reduces particulate production in an engine generator; however, NO_x emissions may increase. Both particulates and NO_x are regulated emissions and a building operator will need to be aware of the implications of their fuel choices. Economic concerns are important for most building operators. A fuel source with a competitive/stable price is highly sought after. As recent history has shown, most fuels do not appear to be immune from macroeconomic price influences as was seen in gasoline and ethanol prices in the late 2000s.

Biofuels can be used to generate heat in boilers or both electricity and heat in engines, gas turbines, etc. Biomass in the form of wood pellets or chips are used with some frequency in residential and some commercial heating applications and a number of manufacturers of pellet and chip burning heating systems are on the market. Larger boilers may use biodiesel in place of fuel oil or biogas in place of natural gas to make larger quantities of heat.

Biofuels have also been used to make electricity and heat in power plants of a variety of sizes. Large amount of biomass such as sawdust are burned in boilers to make steam to drive a turbine, which in turn generates electricity. Smaller applications include using biodiesel, ethanol, and biogas in engine generators and gas turbines to provide backup power or primary power and heat. Similar to the wood chip and pellet burning, there are several manufacturers of engines and gas turbines that offer systems capable of using biofuels for building applications.

Introduction

Biofuels have been used for thousands of years to make heat and light; however, recent political, economic, environmental, and security concerns have refocused the world's attention on biofuels of all types.

The majority of attention is focused on biofuel for transportation purposes; however, as the U.S. Department of Energy has stated that, 40% of energy consumption and emissions come from building operations [1]. To alleviate the environmental impact of building operations, world governments, researchers, and building designers are looking for ways to reduce the carbon footprint of buildings as well as finding alternatives to dwindling supplies of fossil fuels required to operate modern buildings.

The building owner/operator should be aware of the entire life cycle of the selected biofuel to avoid any operational disruptions of embarrassment that may arise from a less efficient part of the biofuel delivery process. For example, high-quality palm oil may be very desirable for a boiler. However, if that palm oil comes from a plantation, where a rainforest once stood and was burned to the ground, the environmental benefit of that palm oil would be in doubt.

The life cycle of a biofuel is broken down into five parts, each of which has several considerations:

- Growth
 - How fast does the feedstock grow?
 - How much energy is derived per pound of plant material?
 - How much energy does it take to produce the plant material?
 - Where does the plant material grow?
 - What grew in this location before the biofuel crop?
- Harvest
 - What methods of harvesting the plant material are used?
 - Does the method of harvesting use more energy than the biofuel generates?
- Refining
 - Does the refining process generate large waste streams?
 - How much energy does the refinement process consume?
- Distribution
 - Does the shipping of the biofuel consume more energy than the biofuel generates?
- Use
 - How efficiently is the fuel being burned?
 - Is the fuel being burned cleanly to meet emissions standards?
 - Is the fuel being stored properly and safely?

The building owner/operator is most directly impacted by the “Distribution” and “Use” phases of the life cycle analysis, but as stated other parts of the life cycle may be significant to the user of the biofuels and undermine their broader sustainability goals.

Growth

Different sources of biofuels grow at varying rates, in varying conditions, with varying amounts of required resources. Needless to say, not all biofuels are created equally. For example, Fig. 1 shows the quantity of oil per unit area for many different types of crops. See reference for a more complete listing of plants.

While the actual input energy for growing an acre of crops varies depending on location and technology, it is clear that some crops are better than others for creating

Plant	Latin Name	kg Oil/hectare	lb Oil/acre
Corn	Zea Mays	145	129
Palm	Erythea Salvadorensis	189	168
Cotton	Gossypium Hirsutum	273	243
Soybean	Glycine Max	375	334
Pumpkin Seed	Cucurbita Pepo	449	400
Mustard	Brassica Alba	481	428
Sunflower	Helianthus Annuus	800	712
Peanut	Arachis Hypogaea	890	792
Opium Poppy	Papaver Somniferum	978	871
Rapeseed	Brassica Napus	1,000	890
Castor Bean	Ricinus Communis	1,188	1,058
Jatropha	Jatropha Curcas	1,590	1,416
Coconut	Cocos Nucifera	2,260	2,012
Buriti Palm	Mauritia Flexuosa	2,743	2,442
Macauba Palm	Acrocomia Aculeata	3,775	3,361
Oil Palm	Elaeis Guineensis	5,000	4,452

Biofuels and Sustainable Buildings. Figure 1

Average production rates of vegetable oils by plant type [2] (1 kg/ha \approx 0.9 lb/acre)

energy and the users of this energy should be aware of their impact. This same concept applies to biomass and biogas, where there can be great variability depending on the feedstock, which should be discussed with the fuel supplier.

Refining

Most of the processes to create biofuels are conceptually simple; however, the creation of high quality, certified biofuel typically requires specialized equipment and skilled personnel to carry out the process. The text below will outline the basic process for refining biofuels; however, the refinement steps required to make certified fuels are typically much more demanding.

Biomass

When using biomass as a primary energy source it is best to refine the fuel somewhat rather than just cutting down a tree and throwing it into a fire. Most biomass contains a significant amount of moisture, which reduces combustion efficiency and increases particulate and carbon monoxide pollution. As the moisture in the wood evaporates due to the heat from the fire, it displaces oxygen thus reducing the combustion efficiency, which is directly related to the amount of oxygen available. Therefore, wood is often dried prior to being supplied for use in commercial boilers.

In addition to drying the biomass, it is often pelletized or broken down into smaller pieces or chips. This simplifies distribution of the product and simplifies automatically feeding the biomass into boilers. Making smaller pieces of wood also aids the combustion process by making it easier for air to get to the fuel for burning cleanly.

There are many other types of biomass that have various refining methods, from sawdust at lumber mills to grass clippings and tree trimmings burned in an incinerator, but these are more customized systems. The wood chip or pellet burning boilers are the most common application of biomass fuel use in buildings.

Bioliquids

Bioliquids (biodiesel and ethanol) are more complex and require a basic knowledge of chemistry. Ethanol is made like any consumer alcohol through fermentation of sugars. Most commonly these sugars come from corn or sugar cane. The ethanol is then denatured to prevent the ethanol from being used in food products to avoid alcohol taxes which would significantly alter the price of ethanol.

Pure ethanol can be used directly in some engines; however, more commonly an 85% ethanol/15% gasoline mixture known as E85 is sold in the USA and can be used in vehicles with flex fuel engines. Flex fuel engines are defined as engines that can use multiple fuel types and grades. Currently, all modern vehicle engines sold in the USA can already accept up to 10% ethanol mixed in with the gasoline.

At this time there are no commercially available E85 boilers or generators; however, ethanol is the most common biofuel available in North America with its primary use for transportation.

Biodiesel is also mostly used for transportation purposes; however, more boiler and generator applications exist as it is more similar to standard Diesel fuel than E85 is to gasoline. Biodiesel is refined in a process known as transesterification. This process includes combining almost any vegetable oil or animal fat with an alcohol and a catalyst. The types of oils used are known as triglycerides, which are long-chain fatty acids joined by a glycerin backbone. Some of the most common alcohols used are ethanol, butanol, or methanol.

The catalyst, typically sodium hydroxide or potassium hydroxide, speeds up the reaction which separates the esters. The chemical equation below depicts the basic transesterification process.

Equation 1: Basic transesterification process [3]

The two most important effects of the transesterification process are to reduce the freezing temperature of the ester and to reduce the viscosity of the ester so it can be used over a wider range of temperatures. Some older diesel engines have been observed running on heated, unaltered vegetable oil; however, newer high-precision engines require higher grade fuels, which the transesterification process provides.

Once the transesterification process is complete, a neutralizing acid is added to the system to cause the potassium or sodium to precipitate, which simplifies the processes of removing it from the biodiesel. Furthermore, the biodiesel is washed with water to remove excess alcohol from the biodiesel.

Equation 2: Neutralizing step for the transesterification process

There are dozens of proprietary processes used commercially that have reduced the refining time and improved the yields of the refining process; however, that is beyond the scope of this entry.

Biogas

Biogas can often be found on farms, landfills, and wastewater treatment plants. The process is complex but primarily involves capturing, cleaning, and dehumidifying the methane gas that is generated from decomposing organic matter.

As methane is the primary component in biogas as well as natural gas, it can be considered a direct alternative if the biogas has been sufficiently refined. A large portion of the biogas refining process is removing siloxanes and moisture from the gas, which can cause engines and boilers to fail prematurely.

There are many commercially available boilers, engines, and gas turbines that will run off less refined biogas; however, there is a cost premium due to more

expensive materials. Therefore, a balance must be struck between refining and use.

Typically biogas refineries collect a significant amount of biomass such as municipal waste treatment facilities, landfills, and farms. It is difficult to justify the installation of such a system if little biomass is available. Working with the local gas company to find a supplier of biogas may be an alternative approach to supplying your building's systems with biogas. Figure 2 shows a system that is being constructed in 2011 to supply a university with biogas from a municipal landfill.

The system shown in Fig. 2 is being built in stages with the landfill flaring system being constructed first. The advantage of building the flaring system first is to determine how much gas is available before selecting

Biofuels and Sustainable Buildings. Figure 2
1 MWe landfill gas cogeneration system [4]

Biofuels and Sustainable Buildings. Figure 3
Biomass gasification system [5]

the pipeline and plant size. The quantity of gas production is very difficult to predict as the exact type of waste deposited in the landfill over the last 25 years is unknown.

An alternative system is a biomass gasification system that uses wood chips and process known as pyrolysis, which burns wood chips in an environment with little oxygen as shown in Fig. 3.

The balance of the biomass gasification system may use boilers or engines coupled with heat recovery, which will be addressed in later sections.

Owner/Operator Concerns

The day-to-day operations that effect building owners and operators include the supply, storage, use, emissions, and cost of the biofuel. As stated, the issues discussed in the background section should be of concern to the building owner in a holistic sense, the

following sections will describe some of the challenges and considerations that directly impact the building owner and operators as well as the design team.

Supply Chain

Establishing a steady supply chain for biofuels is of vital importance to the successful operation of any system. Unlike fossil fuel distribution infrastructure, biofuel distribution infrastructure is limited and may be unreliable in certain areas for certain fuel types. There is a growing body of trade associations for commercial biofuels that can assist building owners in establishing a steady supply chain [6–8].

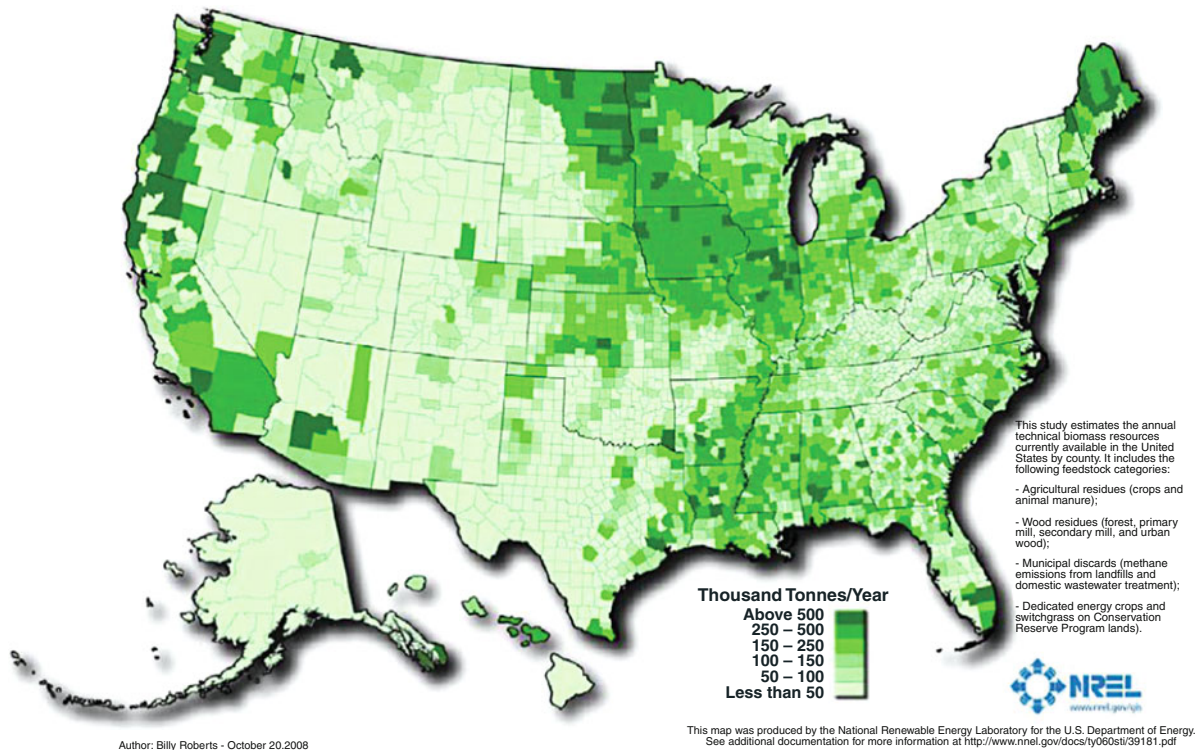

An alternative to commercial biofuel supply is to establish an independent biofuel infrastructure. Building designers and owners should be aware of nearby resources such as farms, waste treatment facilities, and/or cafeterias/restaurants that generate significant resources that could be converted into biofuels. While it is complex and expensive to setup independent refining facilities, it may be cost and environmentally beneficial in the long term. If it is financially feasible, a backup fossil fuel system may be desirable.

As stated in the refining section, certified fuel is often required for most biofuel burning equipment. It is important to verify that the fuel supplier is meeting the most recent fuel quality standards. The most recent standards can be obtained from the biofuel trade associations [7, 8]. These standards continue to be under development and receive frequent updates as the modern biofuel industry is not as mature as the fossil fuel industry. It is essential that fuel specifications are passed on to the boiler, engine, or turbine manufacturer to determine if the performance estimates are accurate as well as if the fuel will void the product warranty.

While getting biofuels to your site is a challenge, the U.S. Department of Energy's National Renewable Energy Lab (NREL) has assembled a map to assist biofuel users in determining where high concentrations of biofuels are likely to exist. Figure 4 below shows the approximate quantity of biofuel generated per year by location.

Fuel Delivery and Storage

Fuel storage is often a necessary part of biofuel systems, and there are a number of considerations to be

Biofuels and Sustainable Buildings. Figure 4
Biofuel potential by county for the USA [1]

investigated. First and foremost are fire code requirements, as biofuels, while often safer than fossil fuels, still pose a significant risk. The fire code is doubly important if fuel refining is done on-site as well. Local fire codes may not address biofuels and therefore fossil fuel requirements may be applied or a state fire code. Most biofuel trade associations will provide some assistance in the areas of fire safety.

The first step in storing fuel is getting the fuel from the delivery vehicle to the storage tank. For the biodiesel and ethanol, modified gasoline and diesel delivery vehicles are typically used, and are frequently available due to the large gasoline and diesel fuel infrastructure that exists. Again, local codes will designate safety features required to fill the storage tank. Independent biogas delivery is often done the same way as a standard natural gas line.

Wood pellets and chips vary in delivery methods. As such, the fuel transfer and storage system should be coordinated with the fuel supplier prior to design and construction. Some suppliers bring trucks that literally

suck pellets out of the truck via hose and shoot them into the storage container using compressed air. Other methods include small dump trucks that pour the chips or pellets into a trough where an auger will transfer the chips or pellets into a storage tank.

Biogas is rarely stored on-site as the process of getting it to site is somewhat complicated and dangerous. First, the biogas is pressurized and bottled off-site by the biogas producer. The biogas bottles are then transported by truck to the building site and stored until needed. The biogas bottles require the necessary gas regulators and explosion proof equipment to distribute the biogas to the boiler or engine that it will fuel. Biogas systems like this are typically reserved for experimental systems.

Sizing the storage tank is a function of first cost, delivery cost, and rate of fuel consumption. It will be an iterative process to balance these criteria as delivery costs and the rate of fuel consumption will vary over time as it is a function of load, which is difficult to project accurately, and projections are very difficult to

make accurately. The larger a storage tank, the higher the first cost both in construction and physical space required.

Once the storage size is known, the tank materials must be selected. While no exotic or expensive materials are required to store most biofuels, some common materials can cause issues.

Wood pellet and chip storage should be in a dry, weather-protected location. However, the spaces do not need to be conditioned by mechanical systems.

Brass valves and some elastomers (rubber) used in seals may be problematic over time for ethanol and biodiesel. The U.S. Department of Energy, National Renewable Energy Laboratory has published material compatibility documents for both ethanol and biodiesel [9, 10].

Biofuel Use

The use phase of biofuels is often of greatest interest to the building owner/operator. Biofuels can be used in boilers and hot water heaters, reciprocating engines, gas turbines, and fuel cells. Most equipment manufacturers have standardized their products to work well with existing technology, making retrofits and new designs relatively simple.

Boilers/Water Heaters Boilers and water heaters are available to be used with almost any biofuel. The most common commercial products are wood pellet and chip boilers for residential use. However, larger commercial boilers are becoming more common as fuel availability, delivering, and automatic feed systems have become more refined. The smaller residential units are typically available as packaged systems and are relatively easy to install. The larger commercial units are more complicated to install as storage and delivery systems need to be tailored for each site.

Fuel oil and natural gas boilers and water heaters may also be available in biodiesel and biogas variants on a case-by-case basis. The performance of these systems will vary based on the manufacturer, but in general manufacturers of boilers and water heaters have gone to great lengths to achieve equivalent or better performance than conventional boilers regardless of fuel type.

The only noticeable change will likely be in the quantity of fuel burned to achieve the same output. For example, the energy density of pure biodiesel is approximately 5% less than that of standard fuel oil. As such, approximately 5% more biodiesel would need to be burned to achieve the same heat output. That said, all fuels, fossil and bio, have energy density tolerances and vary in quality over time depending on a variety of factors based on the recent inputs into the refining process.

The operators need to be aware that running a boiler in a not so cold month with a lower quality fuel may consume more gallons than a colder month with high-quality fuel. That said, prices should reflect the average value of the fuel delivered over the course of a year. Therefore, the cost per unit energy may be high one month and low the next; so it will balance out. The alternative is testing each batch of fuel to determine its energy density, which would be very costly.

Some issues exist with biomass boilers during low load conditions. Strict temperature controls should be put in place to properly regulate the burning of biomass. Low burning temperatures may cause the emissions to change, and create significant carbon monoxide and particulate issues. This will be revisited in the emissions section, but some manufacturers have addressed this issue in their product designs.

Ash removal is also a concern for biomass boiler operators. Like any fire, a small quantity of ash remains that must be disposed of. In facilities with significant land available, the operators may consider dumping the ash on-site as the plants may benefit from the increased nutrients. Any use of ash on-site should be coordinated with a personnel qualified to understand how the local plants will be effected by mixing ash into the soil. Some plants and soil will benefit, while others may be harmed. Urban users of biomass will need to coordinate waste removal with the local refuse company to verify if ash can be land filled or otherwise disposed of in a safe manner.

Reciprocating Engines, Gas Turbines, and Fuel Cells (Prime Movers) The alternative to burning biofuels to create heat is to use the fuel in an engine, turbine, or fuel cell to generate electricity and heat. The function of these systems is essentially unaltered; however, the performance and maintenance may change noticeably.

As of July 2009, NREL estimated that 10.5 GW of electricity was being generated with biofuels with a total potential of 78 GW [1].

Similar to the biofuel boilers and water heaters, manufacturers of prime movers (engines, gas turbines, fuel cells, etc.) have been addressing the compatibility of their products for use with biofuels. As stated in the boiler/water heater section, the energy density of the fuels may vary and the prime movers are no less affected by this difference. Often fuel pumps and capacities are oversized in many systems to account for peak demand operation. Some of this spare capacity is used to feed more biofuel into the prime mover to maintain the desired power level. For example, a Diesel engine fueled with 100% biodiesel operating at 30 kW (40 Hp) will consume fuel as if it were operating at approximately 32 kW using Diesel fuel.

Table 1 shows a selection of prime movers with some general comparisons.

The exhaust and reject heat streams of the prime mover perform nearly identically to fossil-fueled prime movers [11]. Therefore, converting a cogeneration plant from fossil fuel to biofuel may not require the balance of plant to be altered to maintain functionality.

Changes in maintenance cycles are often the cause of the greatest failures of biofuels. For example, a building operator may have been maintaining backup natural gas engine generators for years. However, if an owner has replaced the natural gas fuel supply with

biogas, the previous maintenance cycles may be completely out of sync with the new reality. If the biogas is not the same quality as the natural gas, and is somewhat more corrosive, the engine seals could break down prematurely or the cylinders themselves could start to corrode. The operator must be vigilant about system performance and perform consistent maintenance checks. Additional equipment may be required to inspect the engine as compared to a conventional gas system. As there are relatively few long-term studies of biofueled systems, it is important for the building operator to coordinate and train with the prime mover manufacturers to avoid potential failures.

Cogeneration Prime movers are often paired with heat recovery systems to make combined heat and power (CHP) systems also known as cogeneration systems. The advantage of a cogeneration system versus grid power and standard boilers is that power plants waste approximately two-thirds of the fuel energy in the form of reject heat. Figure 5 shows the energy flow for the US power grid with approximately 68% of fuel energy being lost in conversion and transmission and distribution losses. With a cogeneration system, the majority of this energy can be recovered for useful purposes such as space heating and cooling.

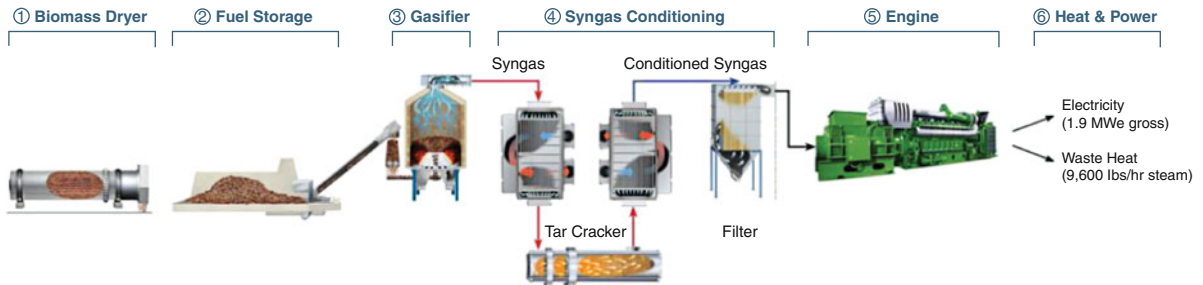

The example shown in Fig. 6 shows a complete biomass gasification and cogeneration plant.

Biofuels and Sustainable Buildings. Table 1 Prime mover comparison by fuel, efficiency, and heat

Prime mover	Fuels	Electrical efficiency	% recoverable heat	CHP efficiency	Heat to power ratio
Boiler + steam turbine	Natural gas, coal, waste fuels, biomass	10–15%	45–65% low-quality steam	65–80%	4.3
Gas turbine	Natural gas, biogas	15–25%	45–55% 600°F exhaust	60–80%	2.8
IC engine					
-Diesel	Diesel, biodiesel	30–40%	15–20% 190°F coolant, 15–20% 900°F exhaust	60–80%	1.6
-Spark	Gasoline, E85, natural gas, biogas	20–42%	15–30% 190°F coolant, 15–20% 900°F exhaust	50–80%	2.0
Fuel cell					
-SOFC	Natural gas	35–45%	25–35% 500°F exhaust	60–80%	0.8
-PEM	Hydrogen	35–45%	25–35% 300°F exhaust	60–80%	0.8

Biofuels and Sustainable Buildings. Figure 5
U.S. Electric grid energy flow [12]

Biofuels and Sustainable Buildings. Figure 6
Cogeneration and biomass gasification plant [5]

This biomass plant includes a substantial amount of conditioning equipment for the synthetic gas (syn gas) created by the gasifier to clean it prior to use in the engine. Alternative systems that use boilers rather than engines may use less conditioning equipment.

Emissions

Emissions are of great concern to many biofuel operators as many emissions are regulated by the U.S. Environmental Protection Agency as well as state

environmental agencies. Of particular concern are NO_x and particulates generated by combusting fuels. Unfortunately, characterization of emissions from biofuels is not a straightforward process. As stated, the quality and type of biofuels can vary and some equipment may not maintain optimal emissions in part load conditions. As such, emissions monitoring may be required for a period of time by local regulators to verify the installation meets local code. This is especially true in emissions non-attainment zones that provide additional focus on individual pollutants.

Biomass Emissions are of particular concern to regulatory bodies when the boilers are operating in part load conditions. As with any fuel, the temperature at which the fuel burns directly impacts the emissions characteristics. As the temperature decreases, carbon monoxide and particulates are formed. There are a number of ways to treat emissions, which include natural gas-fired afterburners to complete combustion and reduce particulate sizes.

Moisture content is also a large influencing factor in the emissions of biomass. Biomass moisture content below 50% is typically required by most boiler and water heat manufacturers [13, 14]. High moisture content will have the effect of boiling the water inside the fuel. As the water is turned to vapor, it will displace the oxygen in the combustion chamber and reduce the completeness of combustion leading to the creation of carbon monoxide. As a rule, the drier the fuel the better, but also the more expensive the fuel will be. Figure 7 shows a comparison of emissions for wood combustion.

Biodiesel Biodiesel can come from many sources including soybean oil and coconut oil. While the thermodynamic performance of these two biodiesel sources may be similar, their emissions characteristics are quite different. As a rule of thumb, soy-based biodiesel,

which is the most common biodiesel source in North America, creates 5–10% more NO_x per kWh than diesel fuel. The emissions characteristics of the biodiesel are dependent on the molecular makeup of the original oil, especially polyunsaturated fat content. Soybean oil has a lot of polyunsaturated fat, as shown in Fig. 8, which indicates that the molecular structure has a lot of double bonds [15].

The consequence of double bonds is that the freezing point is low, which is good, but the cetane number is also low and somewhat unstable in an oxygen environment resulting in increased NO_x emissions [16–19]. Coconut oil on the other hand has very few polyunsaturated fats and a lot of saturated fats. Therefore, coconut oil-based biodiesel has a high freezing point, a high cetane number, is stable in oxygen environments, and has reduced NO_x emissions as shown in Figs. 9 and 10 [16–19].

As the emissions characteristics change per fuel type and content, and the status of pollutants changes per location; the design team must correlate local environmental regulations with available fuel supply to find the right match.

Carbon Neutrality of Biofuels Biofuels in and of themselves are carbon neutral because burning a certain mass of wood to generate heat will release

Biofuels and Sustainable Buildings. Figure 7
Comparison of wood combustion systems [5]

Biofuels and Sustainable Buildings. Figure 8

Fuel properties versus chemical makeup [17–19]

a certain mass of carbon dioxide into the air, which will then be absorbed by another tree to grow approximately the same mass of wood. This cycle is what is typically considered when calculating carbon neutrality and set in comparison to fossil fuels emissions.

However, these calculations often do not include the carbon emissions that are generated during farming, harvesting, refining, and distributing biofuels or fossil fuels. Completing a detailed life cycle analysis to determine precisely how much CO₂ is generated from a fuel can be challenging.

In general, the savings shown in Fig. 11 can be used to estimate savings of cogeneration and biofueled cogeneration versus standard heat and power generation.

Common sense can go a long way in determining the carbon impact of the harvesting, refining, and distribution of a biofuel for a building or campus. If wood pellets are made from waste wood from a nearby lumber mill, then the building owner can be reasonably certain that the CO₂ generated by collecting the waste wood, processing it into pellets, and shipping it the site are relatively small as compared to the boiler emissions.

However, if the biofuel must travel a large distance by truck, in an attempt to offset natural gas delivered via pipeline, then the owner may want to attempt a life cycle analysis. There are a number of sources that

specify how much CO₂ is produced per mile traveled, or per unit energy consumed to assist in calculating a rough life cycle analysis [20–22].

Operating Costs

One of the largest pillars of sustainability is operational cost and operational performance. For owners and operators to be able to maintain effective operation of any system and their business, the following principles are good practices to avoid major cost fluctuations.

Buy Local First, pick the biofuel based on local availability. The distribution infrastructure for many biofuels is still weak, so most biofuels are shipped by truck. A closer supply chain is a great asset, and may give the owner some influence over regulation and pricing with the local government.

Quantify Supply Running out of the desired biofuel is a real concern in many parts of the USA, so it is important to identify multiple suppliers of the desired fuel. It is also important to understand the fuel supplier's supply chain and determine their vulnerabilities. Good things to look out for are large potential biomass sources such as lumber mills, nearby biofuel refineries, and landfills or wastewater treatment facilities. These fuel sources represent significant infrastructural investments and are unlikely to shut down rapidly.

Understand Competition The feedstock cost is the single largest influencing factor in the final cost of the refined biofuel. In 2008, the price of many food crops increased dramatically due to increased worldwide food demand and use of food crops for energy. Similarly, a demand for waste fryer oil changed the way restaurants and cafeterias view this waste stream. Several years ago restaurants had to pay to remove waste grease, then they were able to give it away to ambitious “do it yourself refiners,” and now there is a commodity value to waste grease in some markets where refiners are purchasing the waste grease from restaurants. Identifying potential competition for the biofuel feedstock may alleviate future cost spikes.

Fuel Flexibility Fuel flexibility is the other option to reduce long-term fuel costs. The best example of this

Biofuels and Sustainable Buildings. Figure 11
CO₂ generation of standard systems and cogeneration

concept is the flex fuel engines that run on E85. The E85 engine can run on any ratio of gasoline and ethanol below 85% ethanol. In other words, the fuel tank can be filled with E85 one day, and regular gasoline the next day as desired. Most gas turbines or engines that can run on biogas can also run on natural gas. The same is true for Diesel engines with respect to biodiesel and Diesel fuel. Some boilers can be co-fired natural gas and biomass, but this should be coordinated with the manufacturer.

Fuel flexibility is important in case there is a supply interruption, such as a reduced availability of biomass for the biogas digester, or a scheduled shutdown by lumber mill, or an equipment failure at the refinery. Suppliers may have contingencies in place to provide a supply during shutdowns. Also, building owners/operators may want to include a backup supply that could bridge the gap during outages. The size of the storage is a function of the load and how many days the supply needs to last.

Most fuels are regulated for quality by the American Society for Testing and Materials (ASTM) including ethanol and biodiesel [23–26]. Biogas must meet the local gas company's standards if it is to enter the natural gas network. Similarly, the biomass must meet the boiler manufacturer's standards in order to not void the warranty.

Future Directions

The technology to effectively employ biofuels into mainstream operation exists and has been effectively demonstrated throughout the USA and the world. Significant improvement needs to be made in the area of documentation and education of engineers, owners, operators, and code officials. Like any other industry, this will happen over time as owners request biofueled systems as an alternate to fossil-fueled systems. Owners and governments need to be willing to send their operators and code writers for training to assist in the adoption of these technologies. As owners increasingly demand biofueled systems, building designers, engineers, and the associated services will follow suit to meet demand.

The largest hurdle for the successful long-term operation of biofuels is understanding the minor differences between fossil fuel systems and biofuel

systems. Often building operators will fail to see the subtle difference between the systems that can cause unnecessary problems or failures in long-term operation, and cast doubt on the biofuel industry or a particular technology. As the body of knowledge and experience grows, installers and operators will learn to benefit from the advantages of biofuels and avoid the potential pitfalls to make biofuels as common a part of building operations as fossil fuels are today.

Outside of building operations, continued improvement in supply chain management to keep costs under control will be the largest deciding factor for the long-term success of biofuels. A great deal of research is being conducted to replace the use of food crops as a biofuel feedstock with nonfood alternatives such as wood chips, grass clippings, algae, and other biomass residue as well as increasing the efficiency of refining biofuels.

Biofuels will solve some of the pollution problems faced by the building industry today as well as help diversify the energy portfolio to enhance price stability and energy security. Biofuels along with cogeneration systems will become increasingly attractive as fossil fuels become costlier and environmentally riskier to extract over time. However, biofuels are a commercial commodity and as such will be subject to market forces and the laws of supply and demand. The same price fluctuations that effect transportation fuels today are already starting to affect the biofuel market as demand increases. Owners and operators will need to be aware of where their biofuel comes from as the impacts may be felt more acutely by a local population as opposed to fuels that come from the other side of the world.

Definition of the Subject

Biofuels are liquid, gaseous, and solid fuels derived from biomass based on a broad variety of conversion processes. Despite this definition that encompasses all physical states, the term “biofuels” has been linked throughout the years with the transport sector and considers only liquid and gaseous fuels as an alternative solution to fossil fuels that are used in transport. This entry will follow this trend and will consider under the term “biofuels” fuel options of biomass origin that are used (or intended to be used) within the transport sector. While fossil-based electricity and heat could be replaced from electricity and heat produced from different renewable sources (e.g., sun,

wind), the only way, nowadays, to replace fossil fuels within the transport sector is biomass-based fuels; their importance is therefore undeniable, although their implementation is not free of concerns. The most important drivers for their implementation are the need for diversification of fuel sources, the fluctuations of fossil fuel prices and the associated need for security of fuel supply, and the need for mitigation of greenhouse gas emissions caused by the transport sector. Considering the variety of biomass conversion pathways, this entry provides a comprehensive analysis of current and most promising future biofuels options and highlights technical, economic, and environmental aspects along the entire production chain: from biomass production and transport, over biofuels production and distribution, to the final use of the biofuel (e.g., [1, 2]).

Introduction

Globally, many countries have been motivated to explore alternative energy sources due to increasing fossil fuel prices in average, energy supply security, and environmental consciousness (especially related to climate change). In developed and developing countries, fossil fuel price fluctuations and climate change are driven to the increasing interest in biofuels. Most developed countries are moving from voluntarily to obligatory legislations imposing market shares of biofuels in the transport sector [3]. With careful concepts and appropriate regulations, some biofuels might help to slow down global warming and to enhance energy security. Additionally, biofuels might provide countries opportunities to diversify agriculture production, to raise rural incomes, and to enhance access to commercial energy, especially for rural communities. However, media about the unintended side effects of bioethanol and biodiesel production has dominated the news about biofuels in the past. These headlines range from increasing world hunger and endangering forest reserves to increasing water pollution and wasting public funds [4].

Currently approx. 10% of the global primary energy demand (in 2007 approx. 516 EJ) is covered by biomass [5]. At present due to favorable policies and subsidy support in many countries, bioethanol based on sugar and starch crops (in 2009 approx. 58.4 million tons)

and biodiesel primarily based on vegetable oils (in 2009 approx. 14.4 million tons) are the most common biofuels representing approx. 2% of the total fuel consumption within the transport sector. Globally approx. 110 million tons of bioethanol and approx. 24 million tons of biodiesel are expected to be produced until 2020 which accounts for approx. 3.5% of the total global fuel consumption (Fig. 1).

All over the world, an increasing number of countries define declarations on bioenergy use with special regard to biofuels. Motivations for that are different (e.g., decarbonization strategy in Europe, increased security of supply in America, Asia, and Africa). In Fig. 1, the required biofuels demand according to these biofuel targets is compared to the projected biofuel production and the total transport energy demand according to the IEA reference scenario. Even if assuming that the biofuels targets will be reached fully only approx. 25% of the global additional energy consumption within the transport sector (based on 2005) could be covered by the year 2020. It is expected that in this time frame, biofuels of future generation will only

play a minor role with regard to their current technology status and the expected business-as-usual development.

Against this background, this entry deals with the most important biofuel options for transportation purposes from a current point of view. Based on the characteristics of biomass as a multipurpose resource, technical profiles are shown for the different biofuel options. Furthermore, these technologies are considered concerning economic aspects (e.g., capital investment requirements, costs of production and use) as well as concerning environmental aspects (e.g., global warming effect).

Characteristics of Technologies

Advanced technologies are now under development to convert biomass into various forms of secondary energy including electricity, gaseous, and liquid biofuels. The purpose of biomass conversion is to provide fuels with clearly defined fuel characteristics that meet given fuel quality standards. In general, there are

Biofuels: A Technical, Economic and Environmental Comparison. Figure 1

Comparison of global transport energy demand, biofuel targets, and projected biofuel production (based on [5, 6])

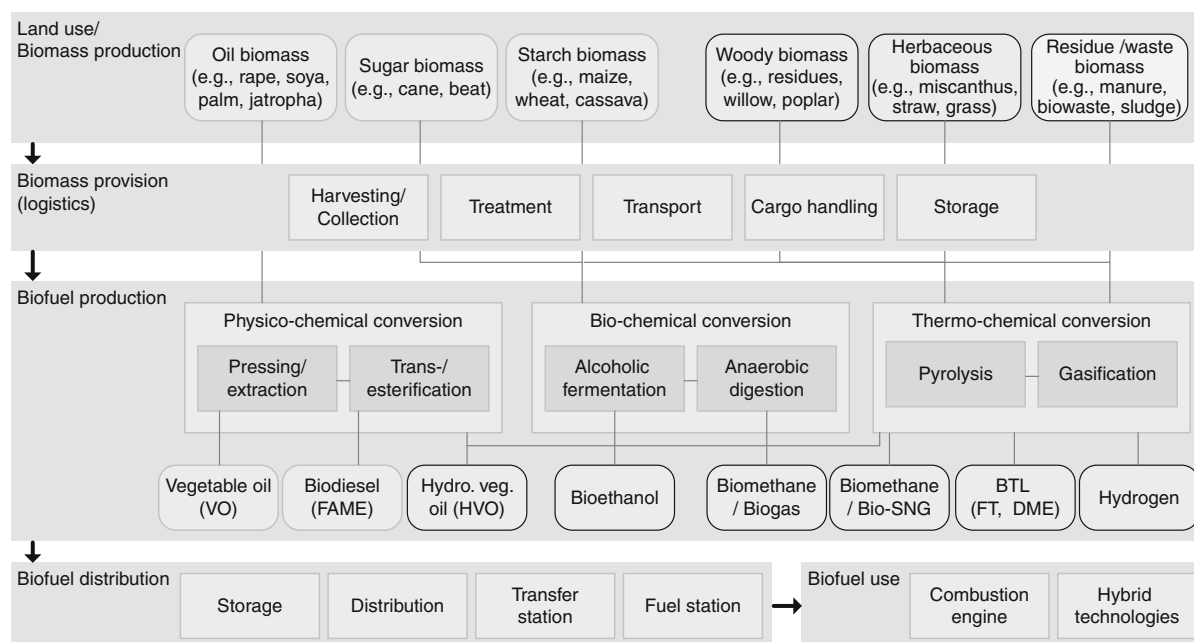

various options to produce alternative transportation fuels based on biomass. Depending on the conversion of biomass in principal, three main conversion pathways come into consideration: (1) the thermochemical pathway, (2) the physicochemical conversion pathway, and (3) the biochemical conversion pathway [7]. An overview is given in Fig. 2. For thermochemical and biochemical conversion, future lignocellulosic options might be promising. The use of lignocelluloses promises a larger non-food crop variety (e.g., woody and herbaceous residues and energy crops) with larger capacities and lower costs are expected at favorable environmental effects in future.

Current-generation biofuels are biofuels currently on the market in considerable amounts. The most important biofuels are bioethanol and ETBE and biodiesel using well-established processes for their production. For these types of fuels, only specific parts of the overall plant are used, such as the starch in corn kernels or grains, the sugar in canes or beet, or the oil in oilseeds. Residues from the production of these crops (e.g., straw) are currently used within the agricultural cycles (e.g., as fertilizer, for animal farming). Moreover, by-products accumulate during biofuel production

and can be applied in the fodder and the chemical industry (e.g., press cake, glycerine, fertilizer when producing biodiesel, and vinasse or DDGS when producing bioethanol).

- Bioethanol is produced by fermenting sugars from starch and sugar biomass (e.g., cereal crops such as corn or wheat and sugarcane or beets). It is applied in pure form in specially adapted vehicles or blended with gasoline, provided that fuel specifications are met. Ethyl-tertiary-butyl-ether (ETBE) is synthesized from bioethanol and isobutylene. It is used as additive to gasoline.
- Biodiesel or fatty acid methyl ester (FAME) made from vegetable oils from the reaction with methanol in a catalyzed transesterification process. It is used in pure form in specially adapted vehicles or blended with diesel.

Different from that future biofuels can basically be produced (1) from an expanded range of feedstock as well as (2) from the whole plant (i.e., much more biomass per hectare land), including biomass waste streams that are rich in lignin and cellulose, such as straw, grass, or wood. It is expected that low-cost

Biofuels: A Technical, Economic and Environmental Comparison. Figure 2

Simplified overview of biofuel pathways (future-generation feedstocks and biofuels marked in green)

residue and waste sources will be the primary feedstock for the next 10–15 years, followed by cellulosic perennial energy crops (e.g., willow, poplar, eucalyptus) with the potential to expand substantially after 2020 [8]. For the provision of these biomass sources, adapted logistic concepts (e.g., with regard to storage, transport, biomass handling) are required since logistic chain complexity increases with increasing biofuel plant size. In order to breakdown this biomass to produce biofuels with better fuel properties than, for example, vegetable oils and biodiesel, two main conversion pathways come into consideration:

- Firstly via biochemical processes that, for example, use special enzymes breaking down the lignocelluloses and releasing the sugars, which can then be fermented into bioethanol. Moreover, biogas that is produced from anaerobic treatment of biogas substrates and is then upgraded to biomethane, which can be fed into the natural grid and, for example, used in natural gas vehicles.
- Secondly via thermochemical processes based on gasification, where high temperatures are used to turn biomass into a raw gas that is treated and conditioned into a synthesis gas, consisting mainly of carbon monoxide and hydrogen. This gas can further be processed into different types of liquid and gaseous fuels via different types of fuel syntheses. Fuels from this route are then called “synthetic biofuels.” Most promising liquid synfuel (also BtL, biomass-to-liquids) is, for example, Fischer–Tropsch fuel due to its favorable fuel properties. Gaseous synfuels are, for example, dimethylether (DME) and bio-SNG, which is also a form of biomethane and can be similarly used as a substitute for natural gas-like biomethane from biogas. Furthermore, available vegetable oils or animal fats can be treated by hydrogenation processes into so-called HVO, a biodiesel with comparably more favorable properties than conventional biodiesel.

Typically, future-generation biofuels production plants and the surrounding infrastructure are more complex than conventional biofuel options and thus more capital intensive (i.e., high capital risk). The technical measures shown with the future-generation concepts are possible in principle but have to be

confirmed within future demonstration plants. Regardless of large differences of the different concepts under discussion, it also has to be pointed out that none of the concepts can be called “proven technology” that can be bought off the shelf as a turnkey plant. Some of the concepts show a promising maturity justifying the development of a first industrial demonstration project together with (industrial) monitoring. Except few demonstration plants under operation (e.g., for HVO, biomethane based on biogas and some bioethanol based on lignocelluloses, mostly integrated into existing conventional bioethanol plant), for all future-generation biofuels scale-up strategies are required. This includes the integration of the different process steps along the complete chain (biomass to transportation fuel) in order to demonstrate the effective process performances and reliability. Thereby the focus (also from an economic viewpoint) must be to achieve industrial reliability and technical performance (energy integration to achieve high efficiency/yields). According to this, it is attractive to build up HVO and BtL plants very close to crude oil refineries in order to use their infrastructure (e.g., with regard to hydrogen supply required for fuel upgrading). Moreover, existing biofuel concepts (e.g., for bioethanol) show the potentials to be a part of the so-called bottom-up approach for biorefinery plants that can function as multiproduct provider (e.g., biofuels, bulk chemicals, fertilizer, energy).

Therefore, enormous R&D&D efforts are required, including the demonstration of the overall chain under industrial conditions (including wastewater management, health and safety aspects, etc.) to prove (1) efficiency, (2) reliability, and (3) operability, also taking into account lessons learned from the implementation of conventional biofuels [6, 9, 10].

Biodiesel

Diesel based on biomass (i.e., biodiesel) can be produced by means of various production routes [1]:

- Via the physicochemical conversion by means of transesterification of vegetable and animal oils and fats; this is the most established pathway for biodiesel worldwide
- Via the thermo-chemical conversion by means of hydrogenation of bio-oils (e.g., palm oil) within

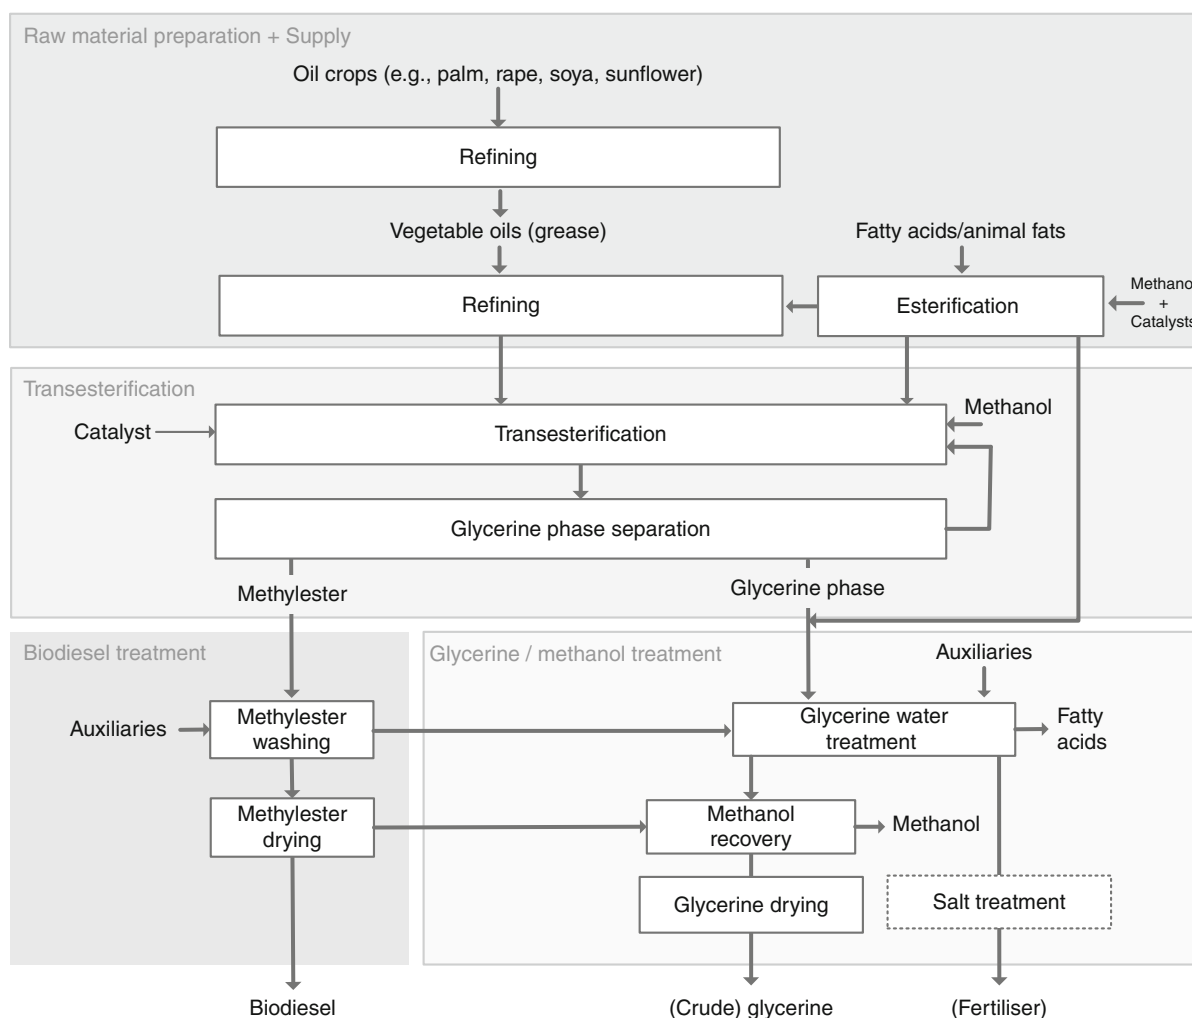

refinery processes that are established for the production of conventional diesel fuel from crude oil; this is still a niche option

Conventional Biodiesel Biodiesel production based on physicochemical conversion typically consists of the production of vegetable oil and fats via mechanical and/or solvent extraction (often within a combined process), followed by (trans)-esterification and the final treatment to biodiesel (Fig. 3). Today, resources for biodiesel are mainly vegetable oils produced from oil-containing crops (e.g., rape seeds, palm fruits, soy

seeds, sunflower seeds). The oil crops (i.e., seeds and fruits) are characterized by a different specific total oil content, which are in the range of, for example, 17% for soy beans (with soy oil as by-product of soy meal production) to about 38% for rape seeds.

Chemically, transesterification (also called alcoholysis) means taking a triglyceride molecule (i.e., vegetable oil) removing the glycerine by substituting with an alcohol (e.g., methanol) and thus creating a so-called fatty acid methyl ester (FAME).

There are three basic steps in the biodiesel production from oils/fats: (trans)-esterification, ester processing, and glycerine purification. Therefore, oil is

Biofuels: A Technical, Economic and Environmental Comparison. Figure 3

Principle of conventional biodiesel production

charged to the reactor and mixed with the alcohol (e.g., methanol) and the catalyst (typically hydroxides like NaOH or KOH or their methylates). A successful transesterification reaction produces two liquid phases: (1) methylester and (2) glycerine. Once separated from the glycerine, the ester is washed to remove any soap formed during the reaction as well as the residual free glycerol and alcohol. The ester is then dried to remove all water. In some cases, the esters are distilled under vacuum to achieve even higher purity in the fuel by removing sulfur and/or phosphorus. The washing step can be greatly affected by the free fatty acids (FFA) level of the feedstock, since all the FFA form soaps in the reaction.

To further refine the glycerine, it is neutralized with an acid to form salts and sent to storage as crude glycerine. Depending on the applied catalyst, surplus catalyst KOH and soaps can be split by producing, for example, potassium sulfate that can be applied as fertilizer. After the aqueous glycerine phase has been neutralized, the glycerine is processed further by evaporation. The glycerine is then typically 60–88 wt.% pure. The glycerine can again be further refined by drying it in a vacuum distillation unit and then cleaned in a continuous adsorption unit to receive technical or pharmaceutical-grade glycerine (up to 99.5 wt.%).

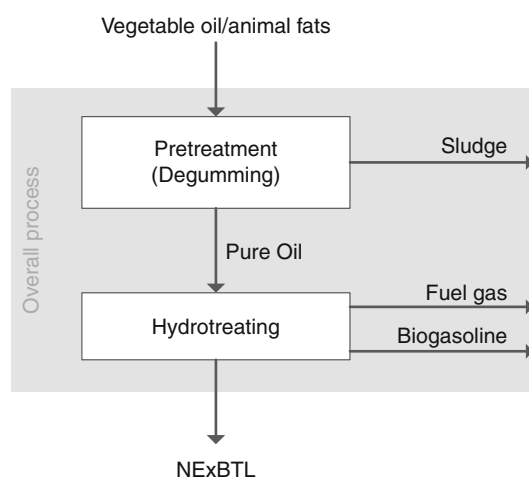

The excess methanol can be removed at different stages of the reaction – before or after the phase separation. In both cases, the methanol is recovered and reused using conventional equipment. Care must be taken to ensure that no water accumulates in the recovered methanol stream.

Depending on application schemes, biodiesel plants are designed in different capacity scales (e.g., from approx. 0.5 kt/a to several 100 kt/a) and performance types (e.g., batch and/or continuous biodiesel processes with or without oil mills as annex plants). The kind and quality of feedstock is the decisive factor for the technical design of a plant and the corresponding material and energy flows [1].

Advanced Biodiesel In order to produce a biodiesel with more favorable properties than biodiesel based on the (trans)-esterification of vegetable or animal oils and fats (i.e., conventional biodiesel production), conventional refinery processes can be also applied to convert the same feedstock into an advanced biodiesel. Properties that are similar to petroleum diesel can be

achieved by blending vegetable oils with mineral oil previous to their upgrading to diesel in mineral refineries by using the existing refinery infrastructure including energy, blending facilities, logistics, and laboratories. One option, which is currently implemented at commercial level is the so-called NExBTL process [11]. The principle of this catalytic hydrotreating process is shown in Fig. 4. It is briefly explained below.

For the pretreatment of the feedstock (e.g., vegetable oils as crude oil, animal fats), conventional degumming technology known from vegetable oil processing or conventional biodiesel production is used to remove undesired impurities [11]. Firstly, the feedstock is filtered before reacting with hydrogen (demand approx. $0.09 \text{ GJ}_{\text{H}_2}/\text{GJ}_{\text{biodiesel}}$ [12]) and passing through the catalyst beds at elevated temperatures and low space velocities. The hydrotreating process typically takes place in fixed-bed reactors at temperatures of approx. 350–450°C and at a partial hydrogen pressure of 48–152 bar. For that, standard catalysts are applied (such as CoMo and NiMo) [13]. During hydrotreating, oxygen is removed by adding hydrogen. Vegetable oil or animal fats (i.e., triglycerides) are converted into three separate branched chain paraffins. Oxygen in the triglyceride is removed as water and carbon dioxide. Side products of the process are fuel gas, which can be used for energy and a small amount of biogasoline. The main product NExBTL has similar

Biofuels: A Technical, Economic and Environmental Comparison. Figure 4

Principle advanced biodiesel production

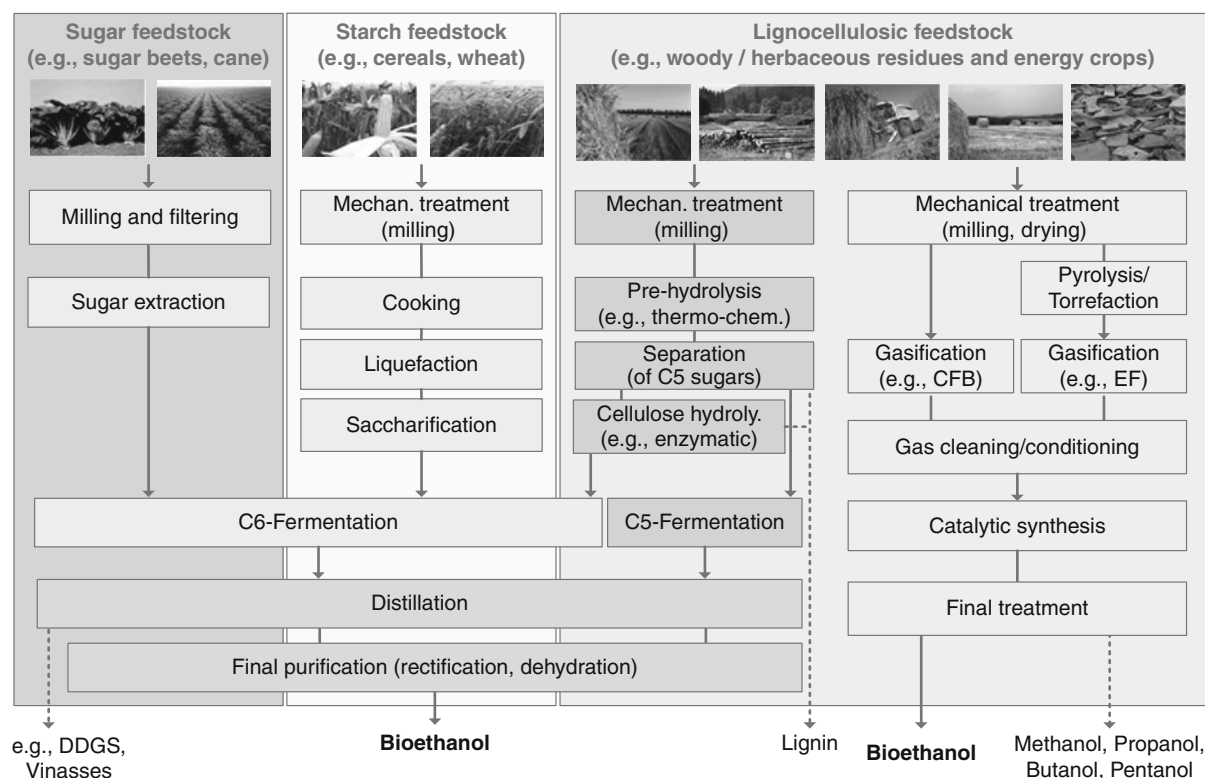

chemistry and properties to the synthetic BtL fuels (e.g., Fischer–Tropsch diesel). The mass specific biomass conversion rate is – depending on the feedstock – approx. $1.23 \, t_{\text{feedstock}}/t_{\text{biodiesel}}$ [11, 12].

Bioethanol

Bioethanol production is based on biochemical conversion processes (i.e., fermentation by microorganisms), which is also considered in the following (Fig. 5). Currently, worldwide conventional bioethanol is produced by using sugar crops (e.g., sugarcane in Brazil, sugar beet in the Europe) and cereals (e.g., corn in the US, wheat in Europe, cassava in Asia). The use of lignocelluloses offers several benefits regarding crop variety, feedstock costs and environmental impacts in the future. Technologies for conversion of lignocellulosic biomass to bioethanol are basically available. However, currently no commercial lignocellulosic bioethanol plant is being operated. The development of cellulosic

ethanol concentrates on three main regions: the US, China, and Europe. Often, second-generation plants (biochemical) are planned as annex facilities to conventional plants. In addition to biochemically fermented ethanol, bioethanol can be produced as synthetic fuel by thermochemical conversion (Fig. 5).

Conventional Bioethanol When using cereals, the first step within the conversion plant is a milling station. Here, the flour is mixed with water and recycled thin stillage to form a mash. By adding enzymes and a thermal treatment at temperatures between 60°C and 90°C, the starch in the mash is broken down to glucose. The sugar solution, originating from the saccharification is cooled down and is transferred to the fermentation vessel. The alcoholic fermentation is realized at 35°C, which is the optimum temperature for the metabolism of the fermenting yeast. Within the fermentation step, glucose is metabolized by yeast to form ethanol, CO₂, and biomass. The CO₂ resulting

Biofuels: A Technical, Economic and Environmental Comparison. Figure 5
Principles of bioethanol production

from the fermentation process is discarded to the environment or can be used to carbonate soft drinks.

After fermentation, raw bioethanol needs to be treated by distillation and final purification (dehydration). In the process of distillation, the alcohol contained in the mash (concentration of up to 5 wt.% [14]) is separated based on a multistage distillation/rectification using steam. Beside water, several other substances are removed from the ethanol. Furthermore, the coproduct mash is gained as distillation residue. The main desired product of the distillation process is azeotrope ethanol with a maximum purity of 97 vol.%. The subsequent process of dehydration is used for further concentration of ethanol (to achieve an alcohol concentration of at least 99.8 vol.%). For that the method of the molecular sieves has detached the older membrane and entrainer distillation. The use of the molecular sieves also allows the dehydration of ethanol with a purity of down to 85 vol.%. Thereby it is possible to save energy in the process of thermal rectification [15–17].

Apart from concentration of the ethanol, the bottoms of the distillation column (stillage) have to be treated. The stillage is virtually free of ethanol, but contains soluble and insoluble organic and even some inorganic material. The first treatment step consists of a mechanical separation with a decanter, which yields the thin stillage and a decanter cake [18]. Half of the thin stillage can be recycled to the initial mashing process, whereas the rest is fed to a series of two evaporators, in order to further concentrate the soluble substances to syrup. Finally, syrup and decanter cake are blended and dried to reduce the water content. The product of this drying step is marketed as DDGS protein fodder (digesters dried grains with solubles).

Lignocellulosic Bioethanol For the following process stages, the lignocellulosic feedstock is pretreated and grinded to a small particle size of approx. 1–3 mm. Depending on the kind of hydrolysis used in the following procedure, a drying of the treated material to a humidity of less than 10 wt.% may be necessary [15].

To make the sugars available for the fermentation step, hydrolysis (i.e., saccharification) is carried out. The first step of hydrolysis contains the release of fermentable monosaccharides C_5 (i.e., xylose, arabinose) and C_6 (i.e., hexose, glucose) from cellulose and hemicellulose. The second step of hydrolysis is typically based on an

enzymatic decomposition of the cellulose molecules. Alternatively, a single step process using concentrated hydrochloric and sulfuric acid could be used for cellulose extraction. Moreover, enzymatic procedures are still in the progress of development [14, 15].

In the next step, the sugars gained from hydrolysis are used as feed for the following process of fermentation. The remaining lignin could be used as a fuel for the production of process energy. Depending on the plant used, the process of fermentation takes between 2 and 5 days. Afterwards, the used mash contains 10–15 vol.% of ethanol. For process control, the used auxiliary materials are important (e.g., acids for the pH-value and ammonia for nutrient supply of yeast). These requirements in connection with an appropriate temperature are the basis of the yeast enzyme production and therewith of the glucose conversion to ethanol and carbon dioxide. For the fermentation of lignocellulose, the commonly used yeast is suitable only to a limited extent. From the contained sugar spectrum, only glucose, as a monomer component of the cellulose molecule, can be fermented to bioethanol. Based on biotechnological methods, new approaches for the fermentation of the whole sugar spectrum produced from lignocellulosic biomass have been developed over the last years [7, 14].

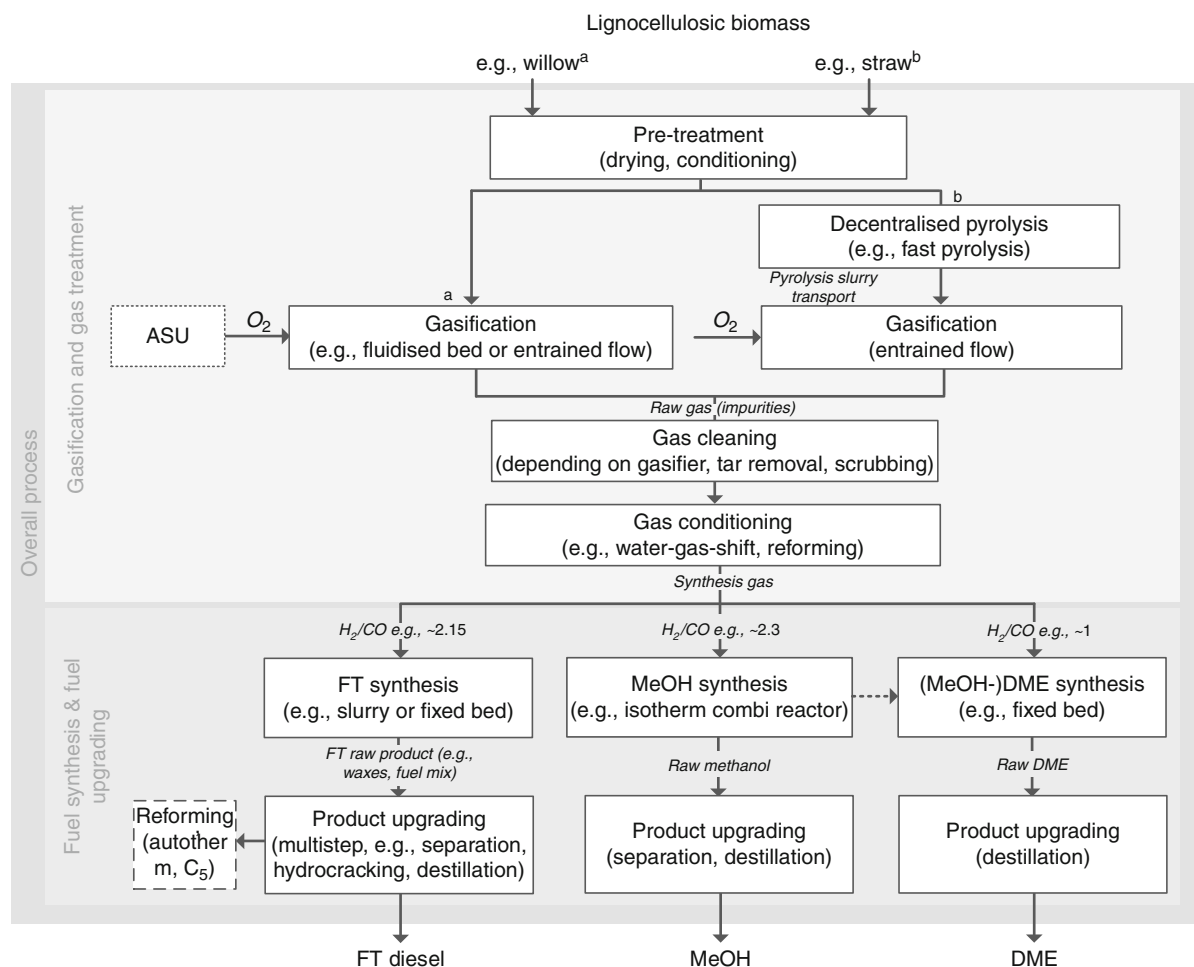

The additional steps for ethanol concentration are basically the same like for conventional bioethanol.

Synthetic Biofuels

The production of synthetic fuels (i.e., “designer fuels” with clearly defined properties) is characterized by three main steps to be performed after appropriate biomass pretreatment:

1. Gasification of lignocellulosic biomass to a raw gas
2. Cleaning and conditioning of raw gas to synthesis gas
3. Catalytic synthesis of this gas to synthetic biofuels (e.g., Fischer–Tropsch fuel, methanol (MeOH), dimethylether (DME), and synthetic natural gas (SNG))
4. Final product treatment

In the following, Fischer–Tropsch fuel (FT), biomethanol (MeOH), and dimethylether (DME) are briefly introduced. The principle is shown in Fig. 6.

Biofuels: A Technical, Economic and Environmental Comparison. Figure 6

Principle thermochemical synthetic biofuel production

Despite of a long history of the development of a broad variety of system elements as well as system layouts for the provision of liquid and/or gaseous fuels via biomass gasification, no market breakthrough has been realized so far. One reason is, for example, difficulties in combining different system elements to an overall turnkey plant. Additionally, some system elements are still under development. For an efficient production of synthetic biofuels with regard to “economy of scale” within the conversion plant as well as the minimization of the biomass transportation costs, conversion concepts of a medium to large scale are required. Such a medium to large scale is necessary to provide sufficient amount of raw gas for gas cleaning/

conditioning and fuel synthesis as well as to produce this gas via gasification at economically justifiable costs.

Regarding biomass pretreatment for gasification, mechanical-thermal biomass treatment (e.g., chipping and drying of solid biofuels) is mature. Processes to produce intermediate products that can be more easily transported and handled for gasification (i.e., pyrolysis and torrefaction) are still in a pilot/demo stage. Despite the scale of a gasifier, no gasification system is a priori appropriate for biomass. Among other criteria, chemical characteristics and physical and mechanical properties of the utilized biomass are of importance. However, all reactors for biomass gasification (e.g., fluidized bed reactors, entrained flow reactor) are still

in an R&D stage up to now. Furthermore, previous developments on gasification were mostly not focused on synthesis gas production but rather on the provision of a product gas intended to be used for heat and power generation.

Depending on fuel synthesis, specific qualities of synthesis gas at constant compositions and large amounts have to be provided (e.g., for the production of 100–1,000 m³_{STP}/h of FT). Quality criteria are, for example, a certain degree of gas purity and a specific H₂/CO ratio. Because so far no gasification system meets these requirements, appropriate gas cleaning and conditioning system have to be applied. During gasification, besides the main components (CH₄, H₂, CO and CO₂) also impurities are generated such as tars, coarse and fine particles, sulfur compounds, alkalis, halogen and nitrogen compounds, as well as heavy metals. Their quantities vary depending on the gasification process as well as the type of biomass. For raw gas cleaning, either low temperature wet gas cleaning or, alternatively, hot gas cleaning can be applied. The effectiveness of wet gas cleaning (e.g., cyclone and filter, scrubbing based on chemical or physical absorption) has been well proven for large-scale coal gasification systems. Contrary to that, not all elements of hot gas cleaning (e.g., tar cracking, granular beds and filters, physical adsorption or chemical absorption, ZnO-bed, physical absorption) are of mature technology yet. Nevertheless, hot gas cleaning offers benefits for the overall energy balance and with regard to the avoidance of contaminated sewage. For gas conditioning, available system components can be applied: hydrocarbons in the product gas can be converted by means of an additional steam or autothermal reforming step resulting in a higher H₂/CO ratio. To achieve the required quality for fuel synthesis, the water–gas CO conversion is conducted as final step of synthesis gas production [19].

The production of synthesis biofuels primarily differ regarding a catalytic exothermic synthesis and product upgrading:

- *Fischer–Tropsch (FT) fuels.* FT synthesis is a polymerization process at low temperature (200–240°C) whereby synthesis gas is liquefied into hydrocarbon chains of different length. This synthesis is catalyzed either by iron- or cobalt-based

catalysts. This conversion can be operated in a “full-conversion” or a “once-through” operation mode by using either tubular fixed bed or slurry bubble column reactor at an operating pressure range from 20 to 40 bars. The FT raw products consist of a wide spectrum of light hydrocarbons (C₁–C₄), naphtha (C₅–C₁₀), the main product FT diesel (C₁₁–C₂₀), and waxes (C₂₁₊) that need to be separated afterwards. Naphtha is a gasoline fraction of minor value and is used as a resource for the petrochemical industry. It can be upgraded to motor applicable gasoline by isomerization. Wax upgrading is done by hydrocracking. Within this catalytic oil refinery process, long-chained hydrocarbons are split into the desired diesel and middle distillates in the presence of hydrogen [20, 21].

- *Methanol.* The operating pressure of methanol synthesis ranges from 45 to 100 bar and the temperature from 220°C to 280°C. Catalysts needed to steer the conversion process are based on copper, zinc, and aluminum oxide. Like within the FT synthesis, in the methanol synthesis two reactor types are commonly used: (1) fixed-bed reactors (e.g., ICI-quench reactor, isothermal reactor, Linde-isothermal reactor, multiple-bed reactor) or (2) slurry reactors (e.g., suspension/slurry reactor). Within the synthesis, several by-products (e.g., DME, alkalis, ethanol, propanol, butanol) are generated in addition to the methanol fraction, which appear gaseous together with unconverted syngas fractions. For separating higher hydrocarbons from the product gas stream, an oil separator is used. Afterwards the raw methanol is separated by condensing, stored and upgraded in a distillation column [22–24].
- *Dimethylether.* DME can be produced via direct synthesis or via indirect synthesis over the intermediate product methanol. For large-scale application, the fully integration of the two process steps, methanol and DME synthesis (i.e., direct synthesis), is very advantageous and the best choice for DME production in terms of efficiency; but this option is still within the R&D stage. Classically two methanol molecules react to produce DME and water, which is removed. The reaction takes place at temperatures of about 250–300°C. Commonly fixed-bed reactors without any special internal heat

exchangers are used. Stoichiometric efficiencies of about 86–88% referring to the raw methanol can be reached. Besides water and undissolved gases, the generated raw DME contains little amounts of ether compounds and alcohols. The gases can easily be removed by reducing the pressure. Subsequently follows the final product cleaning by distillation [20].

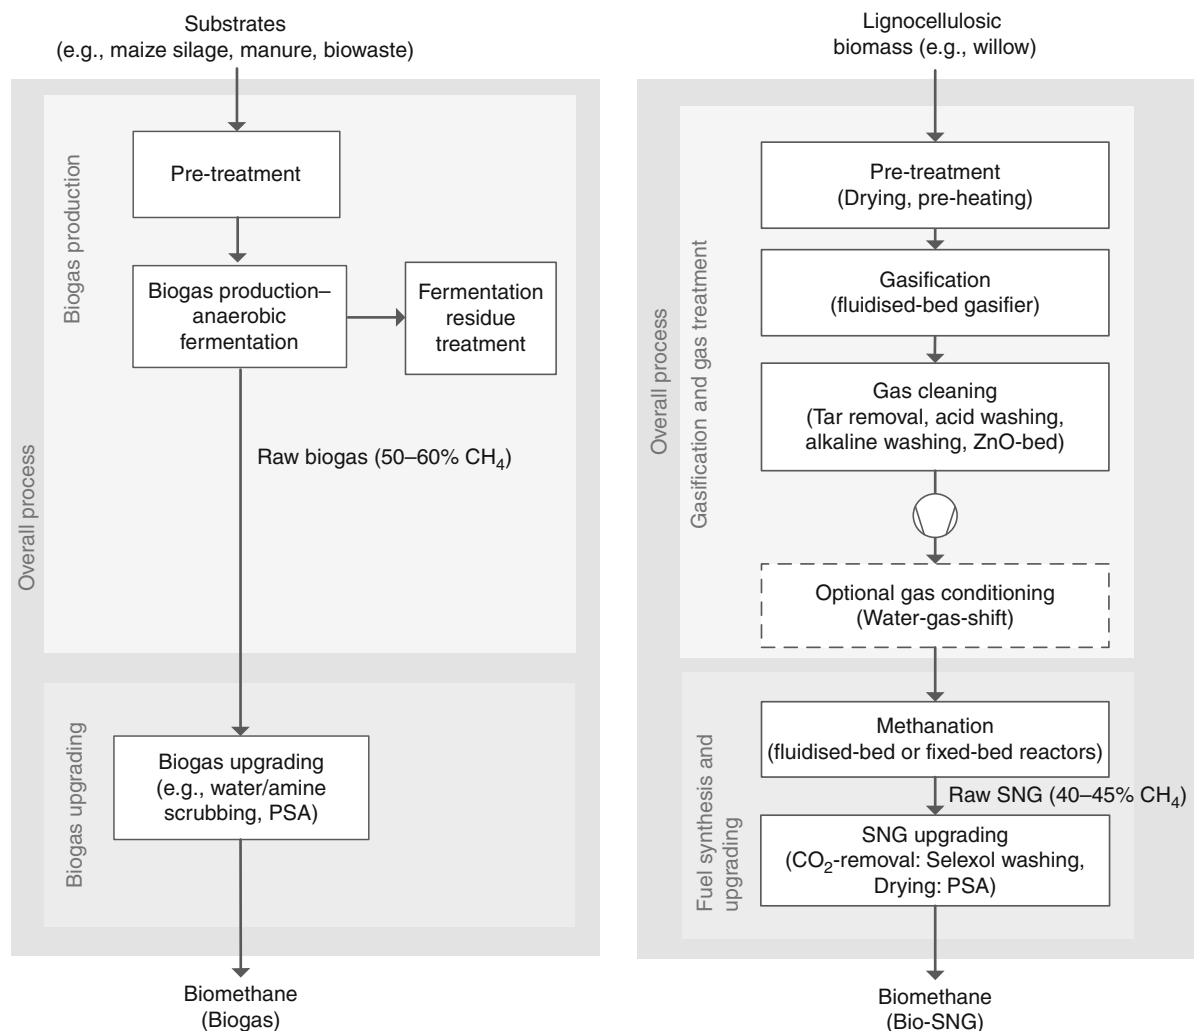

Biomethane (via Biogas and Bio-SNG)

The gaseous fuel biomethane can favorably be applied as a substitute for natural gas. This gas is produced

either through the biochemical conversion of biomass with a subsequent gas upgrading or through the thermochemical conversion of solid biomass via gasification with subsequent gas cleaning, methanation, and product gas upgrading.

In the following (Fig. 7), these two processes are briefly described.

Biogas Biogas production is based on anaerobic fermentation, which requires a substrate pretreatment. On their way into the fermenter, the substrates undergo the following steps: (1) the delivery to the plant, (2) the

Biofuels: A Technical, Economic and Environmental Comparison. Figure 7

Principle of biochemical (left) and thermochemical (right) biomethane production

storage, (3) the upgrading (e.g., homogenization), and (4) the transportation from the storage to the fermenter [25, 26].

For the biogas production by anaerobic fermentation, a broad variety of different kinds of biomass can be used (e.g., liquid and pasty substrates such as manure, biowaste, maize silage, and wastewater). During this biochemical degradation process, organic material is decomposed in an oxygen-free atmosphere by several types of bacteria that produce a gas containing approximately 50–66% methane (CH_4) and 33–50% carbon dioxide (CO_2) plus some impurities (e.g., sulfur compounds like H_2S) of minor importance and water vapor. Digestion is a complex metabolism chain, whereby each step is characterized by the attendance of special bacteria.

In order to feed biogas into the gas grid, the raw biogas has to undergo cleaning and upgrading process steps that include biogas purification from trace components (primarily H_2O , H_2S , and NH_3). Moreover, the heating value, Wobbe index, and other parameters, which highly depend on the CH_4 content, need to be adjusted to pipeline specifications by removing CO_2 . Some technologies enable the removal of H_2S and CO_2 in parallel. However, the relevance, feasibility, and sequence of the different cleaning and upgrading processes depend on the specific gas composition and pipeline specifications. Upgrading technologies for biogas result mainly from technological applications from the natural gas sector where partly comparable upgrading tasks have to be solved, but at a by far larger scale. Main technologies, where already experiences in practice exist, are, for example, water scrubbing, pressure swing adsorption, and chemical absorption (e.g., amine washing). Generally, it has to be stated that all processes available on the market pledge to reach a biomethane quality of more than 96% methane content and a methane loss with less than 3% [27].

Bio-SNG The SNG production is characterized by the possibility that relatively small conversion units with capacities in a range of 10 up to several 100 MW_{th} biomass input can be used. Thus, the conversion of locally available lignocellulosic biomass is possible to minimize the feedstock provision costs. The production of synthetic biofuel, electricity, and heat (so-called tri-generation) allows high overall

efficiencies (e.g., high GHG mitigation potential) within the entire production process. Compared to the production of BtL-fuels (like Fischer–Tropsch fuels) the SNG production system is characterized by lower technical and financial risks due to a technology that is less complex (e.g., synthesis and fuel treatment) and basically smaller units can be used [28].

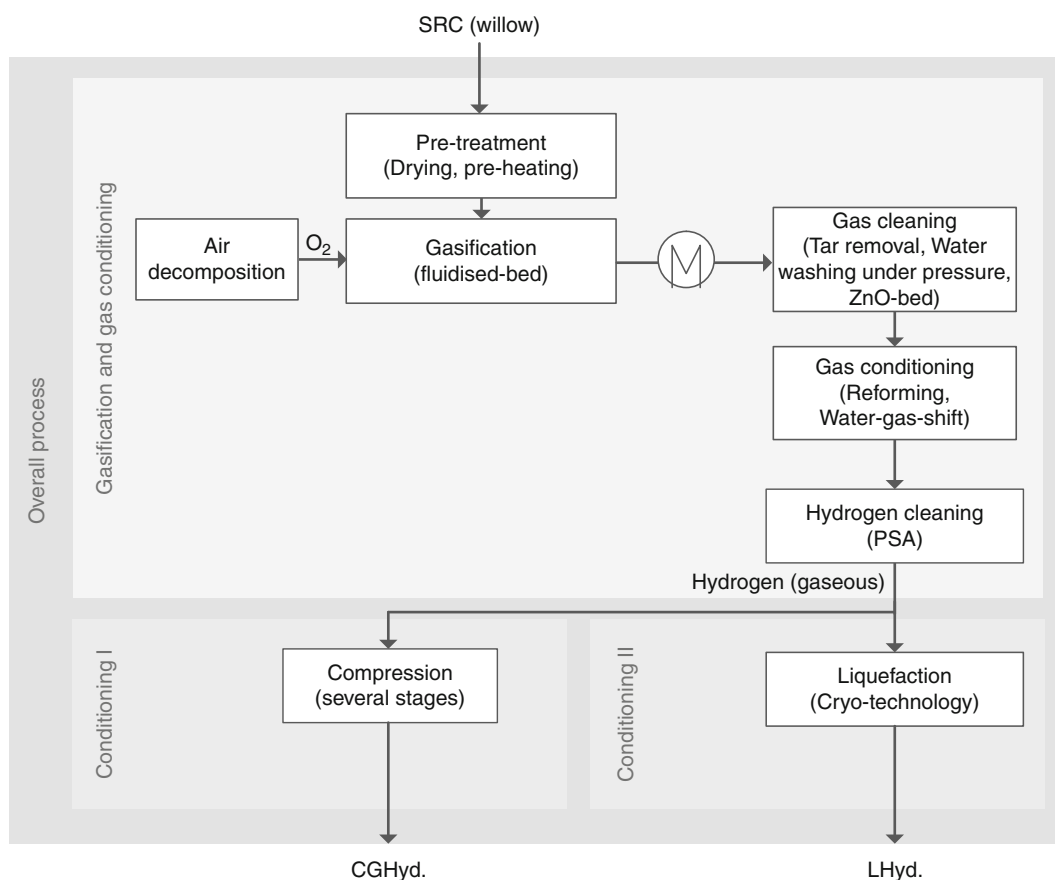

Regarding technology aspects, process steps such as biomass pretreatment, gasification, as well as gas treatment for synthesis are basically similar to that of the other discussed synthetic biofuel options. They have to be adjusted; especially the methanation requires high gas purity grades (nearly sulfur free gas) and a specific H_2/CO ratio.

At present, only the methanation of cleaned and conditioned gas out of coal is state of the art (e.g., SNG plant in US North Dakota with a capacity of 1.5 GW_{SNG} [29]). However, the methanation of gas generated out of biomass is under investigation in several test facilities and show up good results (e.g., energetic efficiencies of about 80%). For a fast and effective conversion, nickel- or copper-based catalysts are used for the exothermal methanation at a catalyst-specific temperature level of 200–450°C and pressures up to 50 bar. For managing the heat, currently several reactor concepts are in use or under investigation: (1) multiple fixed-bed reactors in one row with intermediate cooling or (2) fluidized-bed reactors with internal heat exchangers. Another heat management option is to recycle cold gas and to refeed it into the methanation [30]. The methane content after methanation is in a range of approx. 40–45 vol.%.

For bio-SNG upgrading to biomethane, basically the same is valid as shown for biogas upgrading. However, for CO_2 separation, typical large-scale technologies such as physical absorption processes (e.g., Selexol, Rectisol) and amine scrubber are applicable. Pressure swing adsorption can be used for final gas drying.

Biohydrogen

Hydrogen is basically used as raw material in chemical industries. Due to increasing environmental requirements and consumption of this industry (especially petrochemistry and refineries), the worldwide hydrogen demand is forecasted to increase annually with 5–7% [31]. While currently hydrogen is produced from fossil fuels, in the long run, renewable sources

Biofuels: A Technical, Economic and Environmental Comparison. Figure 8
Principle of thermochemical biohydrogen production

need to be the fundament of hydrogen production. Thereby the hydrogen production via thermochemical biomass conversion (Fig. 8) seems to be one promising perspective. At present, this process is under investigation at the state of pilot plants [32].

Also for hydrogen production, the various process steps (such as biomass pretreatment, gasification, and gas cleaning) are similar to that described above. However, gasification and gas cleaning have to be adjusted to generate a hydrogen-rich gas.

Within the conversion of biomass into hydrogen, no synthesis step is needed. Thus, the gas conditioning to increase the hydrogen content of the producer gas is quite important. For this purpose, two process steps can be applied: (1) an optional reforming step (e.g., via an endothermic steam reforming or an

autothermal reforming) and/or (2) a water–gas shift step. During water–gas shift reaction, part of the CO are converted into H_2 and CO_2 by addition of water-steam [33, 34].

In general, the first subsequent gas cleaning step is the water removal through condensation. In the following, the gas is cleaned by pressure swing adsorption (PSA). The PSA uses the different partial pressures of the gas components to adsorb undesired components. Remaining tail gas can be used for the process heat supply [35, 36].

For the final use of the produced hydrogen, the energy density has to be increased. For this purpose, there exist two common possibilities: (1) multistep hydrogen compression from about 13 to 30 bar to at least around 250 bar and (2) hydrogen liquefaction to

a higher density at final temperature of -253°C and a pressure of 1.2 bar by cryogenic procedures with an energy demand of 10 kWh/kg_{H2} [37].

System-Technological Assessment

Based on the technology characteristics, the biofuel options outlined above are compared based on criteria regarding biofuel production (i.e., stage of development, technical effort in terms of system complexity, expected plant capacity, and overall efficiency) and criteria regarding infrastructure and end use in vehicle fleets. With regard to European conditions, a summary is shown in Table 1.

According to Table 1, each biofuel option shows different benefits and bottlenecks along the overall production pathway. Conventional biofuel options

are already established technologies and hold a certain market share. Most of the future options are in a pilot (i.e., bio-SNG) or demonstration (i.e., lignocellulosic ethanol) phase, with only advanced biodiesel and bio-gas being already commercially available. Future options are linked to upscaled plant capacities that would allow benefiting from economies of scale and thereby balance the increased capital investments; in return, however, such large facilities pose logistical complexities in terms of biomass supply, storage, and handling. Furthermore, all synthetic fuels are linked to increased technical complexity, due to the various steps for their production (i.e., gasification, gas cleaning, synthesis), a fact which also reflects to the final overall efficiency of the processes.

Considering infrastructure, lignocellulosic ethanol has the advantage of the same treatment steps following

Biofuels: A Technical, Economic and Environmental Comparison. Table 1 Comparison of biofuel-specific system technology aspects

Biofuel option	Biomass conversion to biofuel				Infrastructure and use of biofuels

^c(Concept-specific) energetic net efficiency (base current development stage, theoretical considerations)

fermentation like conventional bioethanol (i.e., distillation, purification); therefore, its production could be established adjacent to existing ethanol facilities. Advanced biodiesel and Fischer–Tropsch diesel show very good technical properties that allow them to be blended at any percentage with conventional diesel without the need for modifications. From that point of view, they are considered very promising in terms of infrastructure suitability. This applies also to the biomethane options since both a natural gas grid is already broadly in place and natural gas vehicles are continuously increasing their fleet. The least promising option as it appears from Table 1 is biohydrogen, which requires both high technical effort in terms of production and special vehicle infrastructure (i.e., fuel cells).

Economic Assessment

With regard to requirements for a successful market implementation of future biofuel options, the consideration of economic aspects include the investigation of capital investment requirements, biofuels production costs, and well-to-wheel costs (WTW) at European conditions. This is done for the different future biofuel options in comparison to costs for the conventional biofuels (i.e., biodiesel and bioethanol).

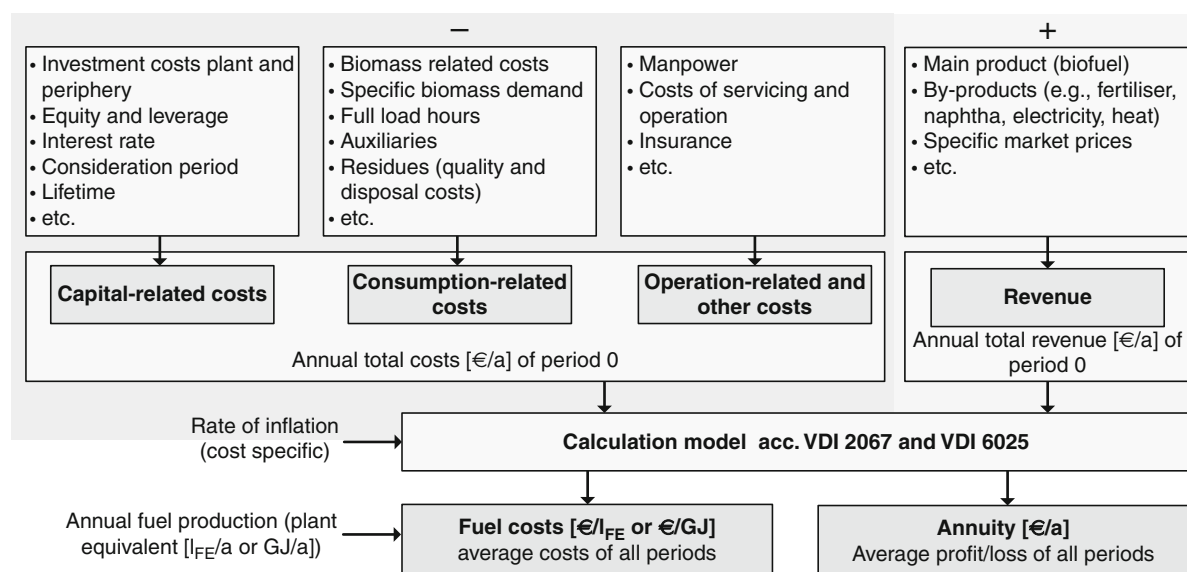

Basic Approach

Typically, economic assessment is aimed to compare different cost alternatives in order to identify relative advantages and determine important influencing factors. Especially with regard to assessing biofuel production costs, dynamic partial models (e.g., based on annuity) can be favorably applied since the accuracy is higher compared to static partial models due to a periodic accounting. The specific cost parameters relevant for biofuel production as well as the basic approach on the annuity model is presented in Fig. 9.

Capital Investment Requirements

Total capital investment (TCI) requirements of biofuels production plants are highly important with regard to financial risks on the one hand side and – as it is the case for more complex biofuel concepts – biofuel production costs on the other.

The determination of total capital investment costs is based on estimations (accuracy of approx. 20–30%) including the method of additional or overhead costs. According to this, plant equipment costs have been determined by up- or downscaling (typical scale factor of approx. 0.7) of existing costs data for similar devices. Moreover, component-specific installation factors

Biofuels: A Technical, Economic and Environmental Comparison. Figure 9

Model for cost calculation of biofuel production costs

(e.g., 1.54–1.66) have to be taken into account. For some components literature data are available; for some components (e.g., that are currently in pilot stage) only rough estimations of technology developers are available. The investment cost figures given were calculated with references from literature. An overview of rough estimations on total capital investment for future biofuel production plants is summarized in Table 2.

With regard to economy of scale, specific total capital investment typically decreases with increasing plant capacity. However, there is a continuous cost increase in the engineering and construction industries, which cannot be reflected at all. The price development of chemical plants and machinery (that also applies to biofuel production plants) is commonly indexed by means of the so-called Kölbel–Schulze methodology. According to this price index, the total capital investment for chemical plants has been increased by approx. 35% in the period from 2000 to 2007.

Biofuel Production Costs

Production costs of future biofuels have been analyzed for exemplary concepts at a database of the time horizon of 2005. The results are summarized in Fig. 10.

As the results of the economic analysis reveal, biofuel production costs show significant differences. Based on GJ fuel equivalent (FE), biomethane options (SNG and biogas) are the most favorable. The sensitivity analyses – carried out for the determination and optimization of cost components that influence the total biofuels production costs – show that feedstock costs (cf. Fig. 11), capital requirements, and the annual full load hours of the plant are strongly important.

Costs for conventional biofuels depend primarily on the prices of agricultural crops, which are relatively volatile and dependent on factors like climatic conditions, agricultural policies, intensification, and mechanization of production. On the other hand, future biofuel options may benefit from the use of residues but this advantage is partially outweighed from the increased supply costs and the more complex logistical aspects as well as the increased capital investments of large facilities. According to the fact that biomass supply depends largely on region-specific conditions, cost

for the provision of biomass to the plants can be from 10% to 60% of total biomass supply (i.e., production and provision) costs depending on the favorable location of the plant and the infrastructure to reach it.

It is expected that biofuel production costs will moderately increase in the future due to rising energy prices with expected price effects (e.g., opportunity costs for feedstock providers in the multi-sectoral biomass market) during broad implementation of biofuel strategies. Crude oil and natural gas prices will largely determine the economic competitiveness of biofuels against fossil fuels and set “limits” for feedstock costs above which biofuels cannot compete with conventional gasoline and diesel.

Based on literature and study survey, the bandwidth of available production costs of biofuel options is shown in Fig. 12. Also other studies show that no significant cost reduction for future biofuels can be expected compared to biofuels of the current generation.

Well-to-Wheel Costs

However, for a market implementation not only biofuel production costs but also total driving costs relating to WTW are of importance for end users. Therefore, with regard to the WTW biofuel costs involving costs of fuel distribution (i.e., via pipeline or tank) and vehicles costs of new private cars (i.e., in combustion and hybrid engines, fuel cells, here estimated referring to [39]), the following results (Fig. 13) can be indicated per vehicle kilometer.

According to this, the differences in biofuel production costs will be lowered in terms of total driving costs as – except for fuel cell application – there is a similar cost range for all biofuels, primarily dominated by vehicle use costs. The costs for biofuel distribution play only a minor role. For a number of reasons (e.g., immature large-scale production), the biofuels of the future generation are significantly more expensive when compared to conventional oil-derived fuels such as diesel at total driving costs of approx. 0.33 €/km.

Environmental Assessment

The favorable political environment of the recent years has led to an increasing use of biofuels in the worldwide transportation sector. This development is mainly

Biofuels: A Technical, Economic and Environmental Comparison. Table 2 Overview of total capital investment for selected biofuel options (based on [6, 14, 16, 20, 38, 39])

Biofuel option	Basic plant equipment	Typical (expected) plant size (MW _{biofuel})	Total capital investment (mn EUR)	Specific total capital investment (EUR/kW _{biofuel})
<i>Conventional options</i>				
Biodiesel	Feedstock refinery, (trans)-esterification, biodiesel washing, by-product cleaning, and upgrading (e.g., glycerine, sulfates, methanol recovery), auxiliaries	4–190	0.9–65	190–340
Bioethanol	Feedstock pretreatment, hydrolysis/saccharification, fermentation, distillation/rectification, final upgrading, by-product treatment (e.g., DDGS, bagasse), auxiliaries	7–220	16–300	1,360–2,290
<i>Future options</i>				
Advanced biodiesel	Feedstock refinery, hydrogenation, product separation, auxiliaries	105–1,030	>100	390–470
Bioethanol	Feedstock pretreatment, hydrolysis/saccharification, fermentation, distillation/rectification, final upgrading, by-product treatment (e.g., lignin), auxiliaries	15–185	30–325	1,800–2,000
FT fuels	Feedstock pretreatment (e.g., mechanical, pyrolysis, torrefaction), gasification, gas cleaning and conditioning, FT synthesis, FT upgrading (e.g., hydrocracking), by-product treatment (e.g., naphtha), auxiliaries	>130–220	430–1,000	2,300–3,480
Biomethanol	Feedstock pretreatment, gasification, gas cleaning and conditioning, methanol synthesis, product upgrading (e.g., separation), auxiliaries	126–270	232–330	1,200–1,800
DME	Feedstock pretreatment, gasification, gas cleaning and conditioning, DME synthesis, product upgrading (e.g., distillation), auxiliaries	130–340	290–350	1,030–2,200
Bio-SNG	Feedstock pretreatment, gasification, gas cleaning and conditioning, methanation, final gas upgrading, auxiliaries	23–170	30–170	1,000–2,100
Biomethane/biogas	Feedstock pretreatment, digestion, final gas upgrading, auxiliaries	5–15	7.5–23	1,500–3,000
Biohydrogen	Feedstock pretreatment, gasification, gas cleaning and conditioning, final upgrading, auxiliaries	140–450	220–450	1,000–1,600

Biofuels: A Technical, Economic and Environmental Comparison. Figure 10

Exemplarily biofuel production costs vs. fossil fuels (refinery product costs)

driven by concerns about the security of energy supplies and the intention to mitigate anthropogenic greenhouse gases (GHG). However, recently, the sustainability of a broad biofuel production and use has been strongly questioned.

To secure especially the reduction of GHG emissions due to the use of biofuels in comparison to fossil fuels and a general sustainability of a broad biofuel production, an expanding biomass usage should also always follow certain sustainability criteria. Next to the environmental impacts related to the biofuel production and usage itself, these criteria should also cover aspects such as biodiversity, the conservation of ecosystems, or the protection of natural safeguards.

As an additional aspect, it is obvious that an increasing use of bioenergy together with a rising demand for food might result in an expanding pressure

on limited land resources. A possible consequence of this development could be the displacement of food production caused by the use of arable land for bioenergy production or an expansion of agricultural production (due to the constant demand for food and feed) into areas not previously used for crop production. Such a development might have direct and indirect effects. While the so-called direct land use change emissions can be calculated and related to a certain biofuel, the quantification of indirect effects is even more complicated.

Within the international context, potential environmental impacts of products (e.g., biofuels) or services (e.g., driven kilometer) are often analyzed with the help of a so-called life cycle assessment (LCA).

Most of the available LCA studies for biofuels focus on the environmental impact categories global warming effect and the primary energy demand.

Biofuels: A Technical, Economic and Environmental Comparison. Figure 11

Exemplarily biofuel production costs depending on feedstock costs and in comparison to mineral oil fuel product costs (typical bandwidth approx. feedstock prices: vegetable oils 600–1,200 €/t, cereals 100–250 €/t, molasses 10–120 €/t, wood 50–150 €/t, straw 0–90 €/t, maize silage 25–30 €/t, based on [6, 40, 41])

Below a brief insight on the basics of the LCA methodology and some exemplary results of existing LCA studies for biofuels are provided.

Basic Approach

The environmental performance of biofuels is often described by the LCA methodology. The LCA method is defined within the international standards ISO 14040 [50] and ISO 14044 [51].

Since the methodology of LCA aims to quantify potential environmental impacts throughout the production, use, and disposal of products, the system boundaries of this investigation are very broadly

defined. They generally comprise the overall product life cycle, starting with the extraction of raw materials ("from cradle") through to the utilization of the product and the disposal of all intermediate or waste products ("to grave"). The emissions linked to all production processes along the product life are considered. Most LCA studies that investigate potential environmental impacts of biofuel systems cover the whole supply chain of biofuels (Fig. 14).

According to the international standards ISO 14040 and ISO 14044, an LCA consists of four major iterative steps: (1) the goal and scope definition, (2) the life cycle inventory calculation, (3) the life cycle impact assessment, and (4) (result) interpretation.

Biofuels: A Technical, Economic and Environmental Comparison. Figure 12

Results of studies on biofuel production costs [39, 42–49]

The goal and scope of definition describes, among others, the underlying questions of the case study and the considered system boundaries and defines the so-called functional unit (e.g., 1 km driven). Additionally, the calculation procedure for the consideration of possible by-products is defined (e.g., allocation or substitution method).

In the life cycle inventory analysis, the inputs of resources, materials, and energy as well as the outputs of products and emissions are investigated and listed for each intermediate step of the production chain. After calculation of all input and output streams, it is possible to identify the amount of emissions related to the overall process chain (including emissions from the production and use of inputs materials and energies).

Within the phase of the life cycle impact assessment, the results of the inventory analysis are associated to specific potential environmental impact categories (e.g., global warming potential) with the help of characterization factors (e.g., the conversion of the different green house gas emissions (GHG) into CO₂ equivalent values using

Intergovernmental Panel on Climate Change (IPCC) characterization factors).

The last phase of the LCA is the so-called interpretation phase. Within this phase, the results of the life cycle impact assessment are discussed and conclusions are drawn [50, 51].

Comparison of Existing Results

Most of the available LCA case studies for biofuels focus on the environmental impact categories global warming effect and primary energy demand. Some results published within the available studies that evaluated greenhouse gas (GHG) emissions per driven kilometer (passenger cars) for conventional and future biofuel options are shown in Fig. 15.

Most of the shown results have been calculated based on the approach of the ISO 14040 and ISO 14044 standard. Since this standardized method is very flexible to allow the assessment of all different types of biofuels under various circumstances and changing conditions, this flexibility can lead to

Biofuels: A Technical, Economic and Environmental Comparison. Figure 13

WTW costs (passenger cars) of different biofuel options

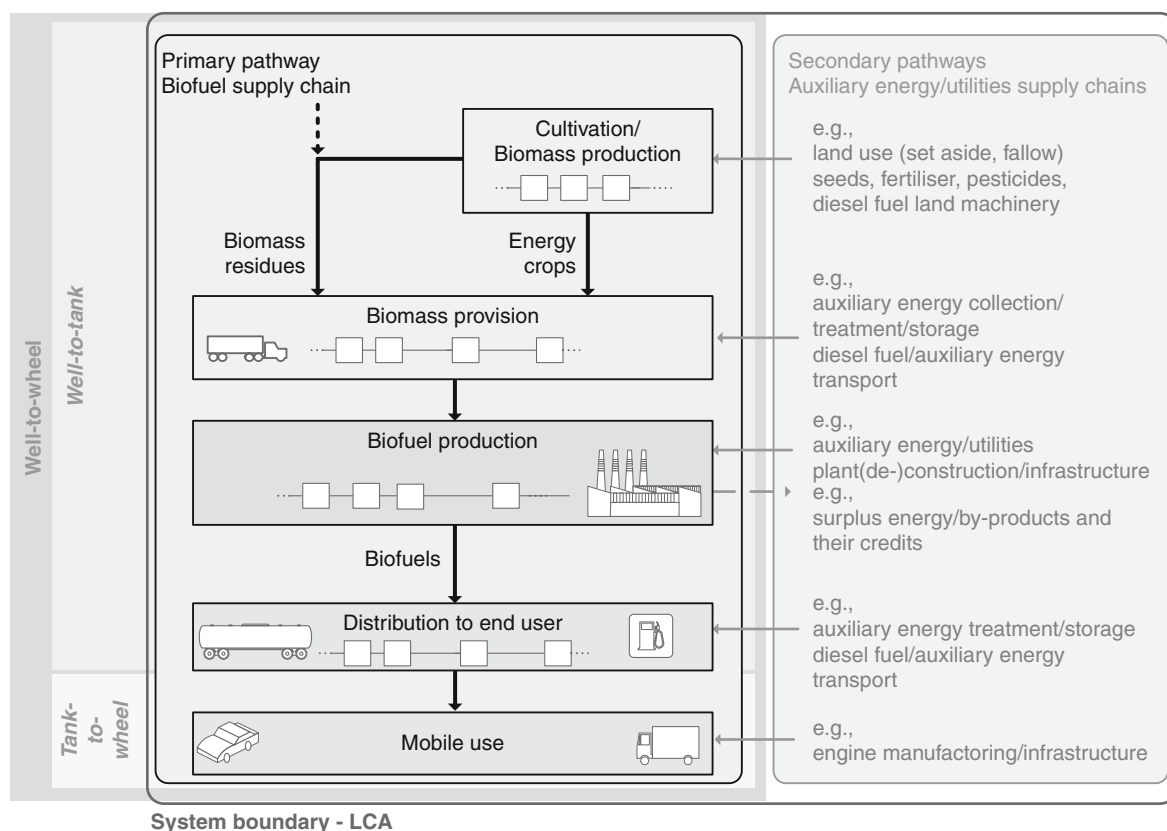

significantly varying results. As a consequence, the results from different LCA studies are in most cases very difficult to compare. This is also true for the results shown in Fig. 15.

As one can reveal there are partly large bandwidths of results for each of the different biofuel options. While current biofuel options show moderate GHG savings (in some cases the GHG emissions for biodiesel and bioethanol are even higher than for their fossil reference fuels), results for advanced and future biofuels show the tendency to increase the GHG mitigation potential. However, the results for the future biofuel options have been calculated for theoretical biofuel production concepts still to be demonstrated at commercial scale in most cases.

The main parameters influencing the total LCA result along the well-to-wheel chain are in most cases the production of biomass resources (especially for energy crops that, e.g., require mineral fertilization) as well as the biofuel production process (especially for concepts with a high demand for external process energy). Feedstock transport to the biofuel production plant as well as biofuel distribution and its use commonly show less negative impacts on the overall result.

Table 3 summarizes the main differences between current and future-generation biofuels with regard to the aspects of land use change and land use competition, feedstock cultivation, and nutrient cycle.

Up to now the majority of the available literature sources do not include effects and emissions from land

Biofuels: A Technical, Economic and Environmental Comparison. Figure 14

Example for an LCA system boundary to assess a biofuel production chain

use change. Land use change can have an effect on the increase or decrease of carbon stored in the vegetation and the soil of the considered area. Therefore, especially the conversion of areas with a high carbon inventory such as primary forests into agricultural areas can lead to significant CO₂ emissions. The consideration of these effects within a life cycle analysis typically will result in negative results and thus in decreasing potentials for GHG mitigation [57].

However, until now international support policies for transportation biofuels have made no or only minor differentiation according to how they have been produced (e.g., regarding environmental impacts). Thus, some governments partly support biofuels that have a higher negative environmental impact than the substituting fossil product. To ensure at least a minimum level of sustainability requirements

for the production and use of biofuels, the European Union introduced different sustainability requirements and standards for biofuels defined within the recently published European Renewable Energy Directive (2009/28/EC). This directive includes standards for a sustainable production of the biomass needed for the biofuel production as well as requirements for a mandatory minimum GHG mitigation. According to this, GHG saving targets or at least a minimum GHG saving for different types of biofuels will be a mandatory requirement at a national and/or European level in the future.

Conclusions

Overall, current biofuels will only provide a niche market (mainly covered by bioethanol and biodiesel

Biofuels: A Technical, Economic and Environmental Comparison. Figure 15

Literature results for GHG emissions (based on EMPA 2007 [52]; EUCAR, 2007 [39]; IE 2004–2007 [53]; IFEU 2004–2007 [12, 46]; Viewls [49]; ZSW 2004 [54]; Macedo 2008 [55]; EU 2009 [56])

until 2020). It is uncertain when next-generation biofuels will be a viable alternative and when significant production can be expected. It is certain that next-generation biofuels firstly will enter the market in the EU or the US before being introduced within developing countries. However, biofuels and bioenergy more generally have to increase in relevance in future in order to meet the energy and environment requirements in an efficient way. It is important to analyze and assess the real potentials of biofuels under consideration of region-specific frame conditions and sustainability criteria, since no biofuel option is suitable for all regions at all.

From a technical point of view, each biofuel option shows different benefits and drawbacks. Thus there is no silver bullet for biofuel; each of them needs to be considered with regard to available feedstock, surrounding available infrastructure, and demand of the market. Current options like bioethanol from sugar and starch as well as conventional biodiesel from oil crops and animal fats are market mature. Options like advanced biodiesel (HVO) and biomethane via biogas enter the market. And production concepts for biofuel option of the future generation are currently in laboratory (e.g., biohydrogen) to pilot and demonstration stage (e.g., bioethanol, Fischer–Tropsch fuel, dimethylether, and bio-SNG). Thus, further R&D&D is required with

Biofuels: A Technical, Economic and Environmental Comparison. Table 3 Main differences regarding environmental impacts of current and future biofuels

Issue	Current biofuels (first generation)	Future biofuels (second generation)
General database	Database on biofuel value chains are available based on practical experiences	Only limited database on biofuel value chains since they have not been demonstrated in practice at present, most of applied data background is based on theoretical concepts
Land use change/land use competition	Land use change has taken place	Potential of land use change, for example, from degraded land to arable land
	Feedstock cultivation on arable land that increase land use competition with food and fodder production	Potential feedstock cultivation (e.g., of perennials) on land which is not suitable for conventional agriculture; decrease of land use competition
		However, land is bounded for several years when applying perennial cropping
Cultivation	Intensification due to increased use of fertilizer and pesticides as well as increased use of water; thus, higher environmental implications	Potential decrease in cultivation due to decreased used of fertilizer, pesticides and water; thus, potential to lower environmental applications
Nutrient and humus cycles	By-products (e.g., straw, press cake, glycerine, fertilizer, DDGS) can be used for farming; thus, potential of closed nutrient and humus cycles	Use of the whole plant for biofuel production may lead to additional expenditures to achieve an well-balanced nutrient and humus cycle
		Usually no by-products that can be applied within the agricultural sector

regard to (1) further development and use of promising biofuel concepts in practice, (2) upscaling to medium- and large-scale plants, (3) the use of approved system components and demonstration of efficient interaction, and (4) plant operability and reliability. For a successful market implementation, existing techno-economic barriers have to be overcome and capital risks need to be minimized.

From an economic point of view, biofuels have so far required state support in order to be cost competitive with current fossil fuels. Feedstock production costs and their dependence on energy prices and climatic conditions are the factor that influences production costs of current biofuels the most (up to 70%). For future biofuels, these costs will play a smaller role, if residues and waste are used as feedstock but the supply and handling of large amounts to upscaled facilities will increase the complexity of logistics and balance this

advantage. On the other hand, dedicated cultivation of lignocellulosic feedstock like short rotation forestry will again add up to the feedstock production and supply costs. Furthermore, the large capital investment associated with large plant sizes increase the risk of investment; therefore, economic viability will require the identification of an ideal location where a secure market for the product and a long-term continuous supply of feedstock can be guaranteed. In addition to that, complex conversion procedures (e.g., simultaneous C5 and C6 fermentation) increase the operating costs and subsequently total production costs. For all these reasons, future-generation biofuels are not expected to be cost competitive at least in the short term. However, ongoing research and development is expected to reduce the conversion costs and allow production in large commercial scale that would allow benefiting from economies of scale.

From the environmental point of view, all biofuels need to be analyzed and assessed regarding their environmental impacts. The political introduction of sustainability criteria for the production and use of biofuels, including minimum GHG mitigation threshold values could lead to a promotion of biofuels with favorable GHG footprints. Concerning these aspects, especially future biofuel options based on lignocellulosic feedstock or residues seem to be very promising. In general, it has to be noted that the current sustainability debate on biofuels is mainly focused on the impact category of global warming. However, an efficient and sustainable biofuel strategy should also consider other environmental aspects such as biodiversity and the protection of natural ecosystems.

Future Directions

An environmentally friendly transportation sector can only be realized by a combination of measures such as the development of new vehicle technologies, the provision of new infrastructure networks, and the application of alternative fuels. Nowadays, biofuels are the only way to substitute fossil fuels and contribute to the mitigation of greenhouse gas emissions within the transportation sector. For these reasons, their role is expected to increase, reckoning at the same time that fossil fuels will remain the dominant fuel option in the near future. Medium- and long-term research is focused nowadays to future-generation biofuels that use also residual feedstock and minimize problems associated with current generation biofuels. Some of these options are in a pilot or demonstration phase (e.g., lignocellulosic ethanol, biosynthetic fuels) and research funding in an international scale in areas like biomass gasification and gas cleaning, methanation, enzymatic hydrolysis of lignocellulose, simultaneous saccharification of C₅ and C₆ sugars will increase the potential for commercial application in the years to come. Other options like biohydrogen are closely linked to the development of vehicle infrastructure (e.g., fuel cells, batteries) and their implementation is interdependent. Similarly, electro-mobility that is surrounded with high hopes requires the development of both the vehicle fleet and the infrastructure network, a fact that places its implementation in the long term.

Of great importance within this context is that electricity is produced from renewable sources, so that electro-mobility actually makes a difference in the transport sector.

On the biomass supply side, future research will focus on the sustainable use of all residue and waste sources for the production of future-generation biofuels. This will be complemented by the sustainable use of land for large-scale production of lignocellulosic crops, such as short rotation forestry or miscanthus; this combination should be able to secure the continuous supply of future-generation facilities that require large amounts of biomass.

Considering sustainability of production and the biomass use itself, the goal for the future is to use the largest possible amount of the initial feedstock, in other words maximize the biomass use efficiency. For that reason, the concept of biorefineries receives nowadays increasing attention and is expected to be the focus of research in the future. Following the example of conventional refineries, biorefineries use biomass as feedstock and produce an array of marketable products by integrating processes and processing all product streams. These products include biofuels, feed, food, heat, electricity, chemicals, polymers, and others. The term “biorefinery” as such is recently introduced but certain facilities that have used this principle are known for years (e.g., pulp and paper mills). Nowadays, the term is expanded and used in a wider sense and a different number of biorefinery concepts have been introduced. Within this context, future goal is to integrate existing processes with new technologies and thereby increase the opportunities for a more efficient biomass use.

Glossary

Upgraded solid biofuel is a solid fuel, which is produced in a technical process, using biomass as feedstock.

Pelletizing is the process of compressing material into the shape of a pellet.

Briquetting is a process of forming briquettes or compacts under pressure with bigger and other sizes than pellets.

Torrefaction is a mild pyrolysis process performed at temperatures between 200°C and 300°C within an inert atmosphere.

Hydrothermal carbonization is a process for the production of a solid fuel in hot pressurized water.

Biocoal is a solid fuel produced by hydrothermal carbonization

Definition of the Subject and its Importance

For the energetic use of biomass, a number of combustion and gasification processes exist. Especially high efficient processes, often developed for the use of coal, have very strict fuel requirements. In many cases, “classical” solid biofuels (like wood logs, wood chips)

cannot fulfill the requirements of these conversion processes. The solution is the adaption of the fuel properties to meet the process requirement by a pretreatment step. The results are upgraded “new” solid biofuels suitable for highly sophisticated conversion processes.

A second driver for biomass pretreatment is the increased demand for biomass as a renewable energy carrier. Therefore it is necessary to utilize also organic mass streams with low quality, e.g., leaves, bark, straw, and hay. Biomass pretreatment alters the transport, storage, and handling characteristics of solid biofuels, as well as their combustion and gasification properties. In doing so, it enables enhanced utilization routes for lignocellulosic biomass resources. Whilst briquetting and pelletizing mainly adapt physical properties of the fuel, torrefaction and hydrothermal carbonization (HTC) also change chemical properties and produce a more coal-like solid biofuel.

Introduction

For the production of upgraded “new” solid biofuel, three main pathways are of major importance:

- Agglomeration as physical process including briquetting and pelletizing
- Torrefaction
- Hydrothermal carbonization as thermochemical processes

Although the products are comparable, the processes have completely different properties.

Briquetting is a well-known process where milled and often fine-particle biomass is compressed interfacially under high pressure. Pelletizing is a process with established technical equipment arising from the animal feed industry. By the end of the last decade, the process was adapted for the production of wood pellets. Today the pelletizing process is of great relevance for the development of alternative biomass pellets (i.e., agro-pellets).

Torrefaction is a mild pyrolysis process performed at temperatures between 200°C and 300°C within an inert atmosphere. Torrefied biomass contains typically 60–70% of the initial mass and 90% of the initial energy content (LHV). Benefits of torrefied biomass compared with green biomass are increased energy density and homogeneity, improved grindability, pronounced hydrophobic character, and enhanced reactivity.

The properties of torrefied biomass allow for the substitution of coal in existing gasification and combustion plants with low retrofitting requirements.

Hydrothermal carbonization is performed in pressurized hot water at 170–250°C using an acidic catalyst. The product is suspended in water resulting in additional efforts for separation and drying. Possible products of hydrothermal carbonization are either functional carbonaceous materials for a variety of applications or solid biofuels with properties similar to lignite.

The main historical keywords for the three pathways are:

- Agglomeration:
 - Briquettes are long-established upgraded solid fuels, especially based on coal.
 - 1970s: first small scale pellet heating units build in the USA.
 - Late 1970s: first pellet plants in Europe.
 - Middle/end of the 1990s: strongly increasing market importance.
 - Today: Wood pellets are a popular fuel for heating systems for households as well as for co-combustion in coal fired CHP-plants in various especially European countries.
- Torrefaction:
 - Last centuries: research on dry thermal upgrading of solid fuels based on charcoal and coke production.
 - Since the 1980s: scientific investigation of biomass torrefaction.
 - 1987: first commercial scale torrefaction plant by Le Bois Torrefie du Lot, a subsidiary of Pechiney (for economic reasons, the plant was decommissioned in the beginning 1990s).
 - Today: commercialization of first plants for pretreatment of biomass for co-firing, gasification, and pelletizing, as well as for better transportation and storage.
- Hydrothermal carbonization:
 - 1913: hydrothermal transformation of biomass into a coal-like product described by Bergius
 - In the 1920s, 1930s and 1960s: ongoing scientific investigation
 - Since 1995: development of a process for the hydrothermal use of waste biomass like sewage sludge by EnerTech (USA) and Mitsubishi (Japan)

- 2008: first pilot-plant employing the SlurryCarb™-process in Rialto, USA
- Today: investigation and commercialization of lower temperature hydrothermal carbonization especially in Germany

Pelletizing and Briquetting

Principles

Agglomeration is defined as a process that brings loose material (particles or fibers) together to agglomerated products with designated form and properties. Caused by the mechanical contact and the physical binding mechanisms a size enlargement compared to the original material is achieved whereas the free particle surface area is reduced. Usually, pressure agglomeration processes like briquetting and pelletizing are used to improve the mechanical and physical properties of solid biofuels. The main benefits of such a compressing are:

- Improvement of the flow, the dosing and conveying properties of the material
- Increase of the bulk density and for this reason reduction within the transport expenses
- Removal of the risk of solidification and bridging of fine bulk solids during transport and storage
- Decrease and removal of dust in the bulk good, reducing dust explosion risks
- Decrease of material loss and prevention of product losses, e.g., caused by oxidation and microbiological decomposition
- Stabilization and homogenization of heterogeneous mixtures of materials, e.g., for the development of blended pellets
- Improved thermal and combustion properties

Briquetting is a common process where milled and fine-particle biomass is compressed interfacially under high pressure. The friction between the material and the press mold releases heat, which activates the binding forces between the particles. The feasibility of briquetting depends on the plasticity of the biomass. The harder and more brittle the material is, the more binding agents are needed to form bridges between the particles. The addition of binding agents is mostly not required for biomass briquetting [1].

Pelletizing is another process for the agglomeration of biomass, where grinded biomass is compacted to pellets by pressure agglomeration. Similar to the briquetting process, the material needs to be plastic or deformable. Friction between the material and the friction channel leads to heat release responsible for the activation of binding forces. Additionally, the material needs an adequate moisture content, which in the easiest case can be achieved by adding water.

Depending on the feedstock and the agglomeration process different binding mechanisms and forces are relevant for the adhesiveness of individual particles (Fig. 1). The understanding of these binding mechanisms during pressure agglomeration is important since optimal particle and fiber bonds in agglomerates cause good physical and mechanical properties. Major binding mechanisms are [2–4]:

- Solid bridges caused by sintering, partial melting, chemical reaction, recrystallization of dissolved substances, hardening binders etc.
- Adhesion and cohesion forces by non-free-moving liquids, highly viscous binders, and adsorption layers (<3 nm thickness)
- Adhesion, surface tension, and capillary pressure by free-moving liquids in pendular, capillary, or funicular state

- Attraction forces between solids – molecular forces like van der Waals forces, free chemical bonds and associations
- Interlocking bonds

The agglomeration of fiber material like wood and herbaceous biomass is mostly based on interlocking bonds. Caused by pressure agglomeration the fibers twist, weave, and bend around each other forming a kind of mesh. Additionally, the formation of interlocking bonds is favored because of the high pore volume. Agglomerates like woody and herbaceous pellets, which mainly stick together by interlocking bonds and which are formed by pressure agglomeration, do not require the use of binding agents during the agglomeration process. However, binders reduce the abrasion of dies as well as the energy consumption. Therefore they are often used.

If the binding strengths achieved by the agglomeration process are too weak, the particle sizes are too large, or certain agglomerate characteristics have to be obtained, additives can be used. Additives are solid or liquid materials causing additional bindings through solid bridges or adhesion forces.

Low viscous liquids like water, which is the cheapest and most common additive, are motile and adsorb on the surface of the particles. If the proportion of the liquid is small, individual liquid bridges develop between the particles. The more fluid disperses between the particles, the higher the cohesion of the agglomerate becomes caused by the capillary pressure. Therefore, steam is used to produce liquid bridges forming solid bridges during the cooling process. Furthermore, steam preheats the material and increases the moisture content. This reduces the energy demand and provides higher stability [5, 6].

However, each process and material requires different moisture levels since too high liquid contents decrease the quality of the agglomerates. In contrast to these mechanisms, binding agents with a high viscosity (like molasses) inhibit the formation of capillary forces. Adhesion forces between the particles and the binding agent are formed instead. Since these forces are more intense, the agglomerates can be more strained. Additionally, binding agents can form solid bridges [4, 7]. Binding agents commonly used in wood pelletizing are wheat, maize starch, and thermally treated starch flour [1].

Biofuels: Upgraded New Solids. Figure 1
Illustration of selected binding mechanisms [4]

Pelletizing and Briquetting Processes

Agglomeration processes consist of individual process steps largely similar for the production of either briquettes or pellets. Figure 2 presents the entire process chains involving several biomass conditioning and post treatment steps.

The pressure agglomeration itself is achieved by applying external forces to particles in different shaped dies to form enlarged agglomerates. Table 1 provides an overview of established technologies.

Briquettes are fabricated either by punch-and-die presses or by extrusion presses. Pelletizing is usually done with roller presses. These roller presses can be subdivided in presses with one or two rollers. Double-roller presses have been originally developed for the agglomeration of coal and are often used for finely divided solids. Because of the low retention time and temperatures non-biomass briquettes can be produced with these presses. The industrial production of wood pellets mainly uses roller presses generally operating with tree rollers; they are called pellet mills or pellet machines.

Properties of Biomass Pellets and Briquettes

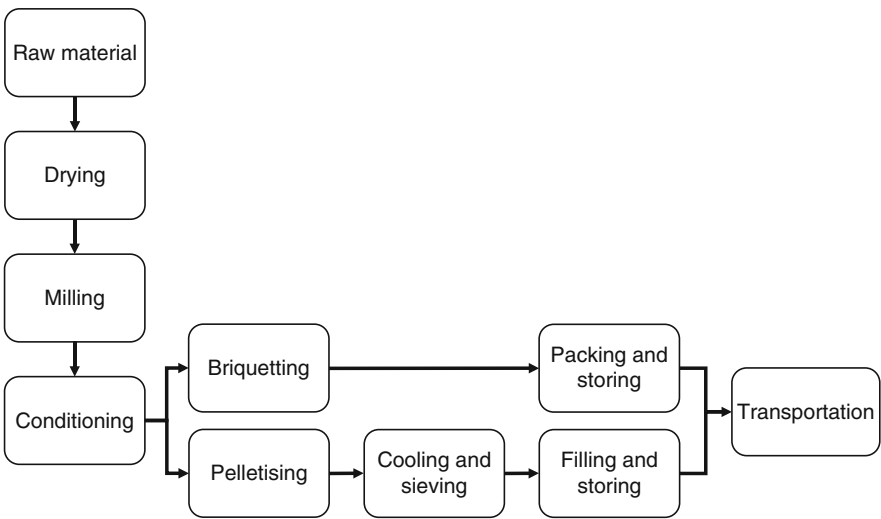

To utilize biomass as a fuel, the chemical properties and the properties like heating value and water and ash content need to be well known. Besides these mass-specific properties, the mechanical-physical properties,

which can be influenced by the compaction process, are of importance (Table 2). Furthermore, these properties are used to evaluate the quality of a compaction process and of the produced pellets and briquettes.

Besides these properties, the physical properties of the raw material like the particle size distribution and the water content influence the quality of the compaction process. Therewith they influence the quality of the compressed fuels similarly to the compaction process.

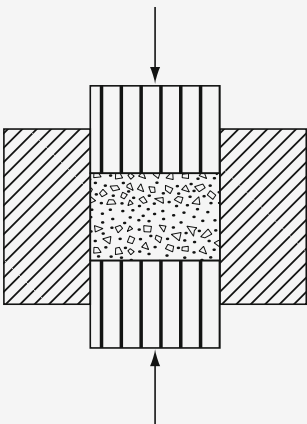

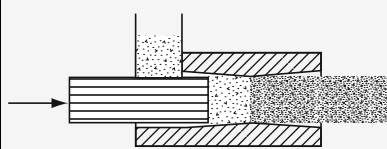

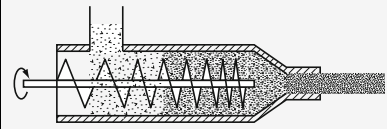

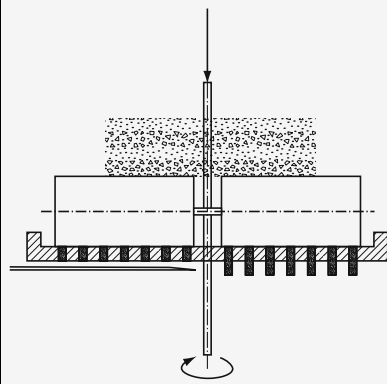

Caused by their great relevance for combustion processes, the mechanical and physical properties of solid biofuels are standardized, like for wood pellets and briquettes in DIN 51731, DIN plus, or ÖNORM M 7135 (Table 3). Currently these values and standards are adapted on EU level in EN 14961 and its quality standards. Besides wood, the standard will also include values for nonwoody biomass pellets not regulated so far. Additional standardization activities have been carried out in some EU countries (like Austria) developing pre-standards like ÖNORM C 4000 for compressed Miscanthus and ÖNORM C 4002 for compressed straw (Table 4). These values are considered to evaluate the quality of briquettes and pellets produced out of other raw materials, like different straw types, hay, and rape press cake (Tables 5 and 6).

The required properties of the above-mentioned standards can be kept if the production process is

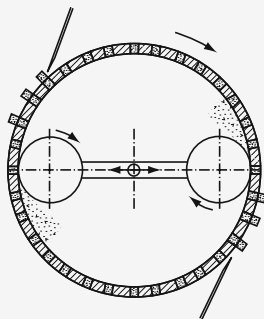

Biofuels: Upgraded New Solids. Figure 2
Production process of pellets and briquettes

Biofuels: Upgraded New Solids. Table 1 Classification of agglomeration processes according to their active principle

Punch-and-die press [8, 9]	
	– Material is compressed with high pressure in closed and differently formed dies
	– One or two punches are possible, usually one punch from above with variable travel
	– Pressure induced hydraulically
	– Low friction, no cooling required
	– Briquettes often rectangular, stackable
Ram extrusion press [8–10]	
	– Material pushed towards a cylinder by a ram
	– Loose material is punched against already initially compressed material
	– Compression and re-expansion leads to plastic deformation
	– Good adjustment of back pressure and friction
	– Briquettes round or of orthogonal profiles
	– suitable for elastic materials
Screw extrusion press [8, 11]	
	– Compression by single- or double-screw extruders where the pressure is generated by decreasing the screw thread
	– Allows high briquette qualities
	– High frictional resistance, higher energy consumption
	– Shape of the briquettes depends on extruder
	– common for animal feed pellets
	– Feed enters the press from above, falls down by gravity and is diverted evenly to the rollers and the track of the die
	– Even material densification, uniform extrusion
	– Pellets are homogeneous
	– Length adjustment by cutters underneath the die

Biofuels: Upgraded New Solids. Table 1 (Continued)

Pellet mill with ring die and press rollers [8, 13–15]	
	– Principle similar to pellet mills with flat dies
	– Ring die is driven
	– Material enters from the front side of the ring
	– Paddles or adjustable plows and three rollers are used to deal with uneven material
	– Internal rollers are moved by the continuous flow of feeding material inside the pellet mill.
	– State-of-the-art for wood pellets

Biofuels: Upgraded New Solids. Table 2 Mechanical and physical properties of compressed fuels with effects to combustion

Parameter	Role in compaction process	Influence on combustion system
Dimension	Regulated by the dimension of the pressing tools	Dimensioning of the feeding system of combustion plants
Gross density	Besides the durability an important measure to evaluate the quality of compacts	With higher particle densities the burnout rate might be increased
Bulk density	Dependent on the quality of the compaction process	Is increasing with increasing gross density; The higher the bulk density the higher the energy density of the biofuel
Amount of fines	Dependent on the quality of the compaction process	Fines cause problems in the combustion process and cause higher dust emissions during transport and handling
Durability	Typically used to evaluate the quality of produced pellets and briquettes (strength, amount of fines)	Risk of failures according to blocking and ash melting by fines

known. However, according to the raw material, the milling grade, and morphological characteristics, the compaction process can be difficult. Nevertheless, the mechanical and physical properties are not directly depended on the raw material. Crucial are the preprocessing of the raw material as well as the process parameters and control of the compaction.

Influencing Parameters for Biomass Pellets and Briquettes

The pellet quality is influenced by several parameters [9, 13, 19]. The raw material composition has the most

severe influence on quality parameters like mechanical durability, bulk density or gross density, followed by the type of conditioning (e.g., preheating and addition of steam), and the milling technology (i.e., particle size and type of mill). The influence of the type of compaction is slightly smaller. Significantly lower is the influence of the cooling after the compaction process.

Raw Material and Raw Material Composition A wide variety of biomass can be used as raw material for the production of solid biofuels (e.g., energy crops like miscanthus, switchgrass and wood from short

rotation coppice, biomass residues like straw, hay, and rape press cake). Several of these materials have been tested for the production of biofuels pellets [16, 20]. Additionally the pelletizing of wheat, barley, soy extraction goat, and alfalfa for animal food applications have been tested [21, 22]. They observed fluctuating mechanical and physical properties of the produced pellets for different raw materials. Additionally, the energy demand of the pelletizing process depends on the raw material [23]. In general, it is more challenging to produce high-quality pellets out of herbaceous

biomass than out of raw materials with a high starch fraction.

Type of Compaction Most of the experiments to determine the influence of the die geometry as well as the compression force on the pelletizing process have been done with ring dies. Longer extrusion channels and smaller diameters result in a higher mechanical durability of the pellets but also cause higher energy demand. The flow rate has a linear relationship with the energy demand of the press [23]. Above a certain point,

the pellet press gets stuck and the material is carbonizes in the extrusion channel caused by too much friction and high temperatures. Generally, the densification ratio (i.e., the length to diameter ratio of the extrusion channels) needs to be higher for herbaceous biomass than for woody biomass, to achieve similar pellet qualities [13, 21, 22].

The compaction pressure in pellet mills is another important parameter influencing the pellet quality [22, 24, 25]. In general, the compaction pressure increases the bulk density of the pellets. The increased pellet durability has been traced back to the softening of lignin present in the pellet at 70°C acting as a binding agent. Consequently, pellets produced at 17 MPa and 75°C are more stable than pellets formed at 55 MPa and room temperature [26]. Thus, the effect of the compaction pressure on the pellet durability is not directly correlated and needs to be verified by further work.

Biofuels: Upgraded New Solids. Table 5 Mechanical and physical properties of different biomass pellets [16–18]

Raw material	Bulk density (kg/m ³)	Gross density (kg/dm ³)	Mechanical durability (wt.%)
Wheat straw	479–620	1.12–1.22	90.6–98.5
Rye straw	510–640	1.28–1.30	94.4–98.7
Hay	580	1.17–1.21	96.2–99.1

Rape press cake	542–607	1.11–1.13	54.9–93.7

Conditioning The raw material for the pelletizing process can be conditioned by influencing the water content of the raw material, by adding binders and additives and by preheating and steam addition.

The optimum water content for the pelletizing process is different for each material. It needs to be verified and to be set by conditioning before the compaction. The optimum water content for wood pelletizing is about 12 wt.%. For herbaceous biomass, it is slightly higher. Experiments with alfalfa showed stable pellets using a raw material with 14 wt.% water content [27, 28]. Similar results have been achieved with reed canary grass where a water content of 14.9 wt.% has been optimal [29]. The water content is adjusted by adding water or steam. When steam is added to the raw material, a second positive effect is achieved; the material is preheated. The durability of blended pellets out of soy meal, ground yellow maize, and ground sorghum has been higher and the amount of fines decreased with higher temperatures at the conditioning process [6]. Additionally, the energy demand of the pelletizing process decreases with higher temperatures, but the overall energy demand of the process increased caused by the energy-intensive steam generation. For other raw materials, similar results were achieved [5, 22, 26, 29, 30].

The addition of binders (e.g., starchy residues like maize gravel, maize starch, rye flour, pea meal, lingsulfonate, or molasses) increases the stability of the pellets [22, 31–33]. Similarly, the addition of soy beans and pyrolysis oil showed positive binding effects and lowered the energy demand of the pellet mill [22]. Other additives (like lime, dolomite, kaolin, and talcum powder) are added during the pelletizing process to improve the combustion properties by

Biofuels: Upgraded New Solids. Table 6 Mechanical and physical properties of different biomass briquettes [13]

Raw material	Length (mm)	Diameter (mm)	Bulk density (kg/m ³)	Gross density (kg/dm ³)	Mechanical durability (wt.-%)
Bark briquettes	205–277	96	–	1.02–1.11	–
Wheat straw	–	15–25	440–493	0.90–0.95	95.2–99.4
Barley straw	–	15–25	318–416	0.80–0.85	97.5–99.0
Hay	–	15–25	412–438	0.95–1.10	90.2–95.0
Miscanthus	–	15	–	1.10–1.40	99.6

increasing the ash melting temperature of the pellets [34–36]. However, the addition of these substances mostly lowers the mechanical durability of the produced pellets. This can be countered by adding an additional binder [16, 35].

Milling Before pelletizing, the raw material needs to be grinded. The type of mill and the milling grade of the raw material are the most important parameters. Raw material such as wheat, barley, and soy extraction goat are grinded by using a hammer mill with a 1–4 mm sieve insert and a roller mill with a nip of 0.75 mm [21]. The grinding with a roller mill was found to be unsuitable for pelletizing. The energy consumption was lower than for the hammer mill but the mechanical durability of the produced pellets was significantly poorer. A higher reduction ratio of the raw material caused a high-energy consumption of the grinding process but a negligible higher durability and no energy saving for the pelletizing process. Similarly, more finely grounded alfalfa resulted in more stable pellets using a hammer mill with 2.0–3.2 mm sieves [22, 28]. In contrast, pellets produced with diameters of 10–25 mm from cut switchgrass and straw had better physicomechanical properties than the pellets produced out of shredded biomass (0–4 mm) [26]. On this basis, it can just be concluded that the required reduction grade needs to be tested for the respective biomass. Indeed, with increasing pellet diameter, a less fine grinding might be sufficient.

Torrefaction

Torrefaction is a mild pyrolysis process for the production of solid biofuels. It is performed at temperatures between 200°C and 300°C within an inert atmosphere. Under these conditions, lignocellulosic biomass is altered to an intermediate between wood and charcoal. After this treatment, the biomass contains typically 60–70% of the initial mass and 90% of the initial energy content referring to the lower heating value (LHV). The physicochemical properties of torrefied biomass are superior to those of the original biomass. Key benefits related to fuel storage, distribution, and utilization are:

- Energy densification
- Homogenization

- Improved grindability
- Pronounced hydrophobic character
- Enhanced reactivity

In the first half of the twentieth century, several patents established the denomination “torrefaction” for the underlying process without leading to commercial installations in that period. Not before the 1980s, growing interest in torrefied wood for applications in electrometallurgy and the domestic fuel market – namely, barbecue fuel – led to the construction of a first commercial plant in 1987 [37]. The continuous process involved chopping, drying, and roasting. Heat transfer has been realized indirectly via thermo-oil. The plant was in operation for a few years.

With the beginning of the twenty-first century, other applications renewed the interest in torrefied wood. Torrefied wood pellets have been identified as a favorable solid biofuel addressing the market of low-carbon fuels for decentralized biomass cogeneration, biomass gasification, and co-firing in coal-fired power plants [38].

Principles

Wood as well as herbaceous biomass is a complex material mainly composed of three sugar-based biopolymers: cellulose, hemicellulose, and lignin. Each of them shows a different behavior during a heating up. Therefore, it is important to distinguish between these fractions to understand the thermal decomposition of woody and herbaceous biomass.

Cellulose is the most common substance in living nature. It consists almost completely of D-glucoses forming an unbranched polysaccharide. On microscopic scale, wood cells are composed of bundles of cellulose, called microfibrils, forming a skeleton. Those bundles are coated with hemicellulose.

In contrast to cellulose, the term hemicellulose subsumes numerous distinct substances. Hemicellulose contains many different sugar monomers forming a branched polymer with an amorphous structure. Its function is manifold, reaching from reinforcing cell structure up to the provision of a reserve substance.

The third main green biomass component is lignin, a three-dimensional cross-linked aromatic biopolymer. Lignin subsumes different heterogeneous substances

that lack a defined primary structure. It acts as a binding agent for the microfibrils; it stabilizes and cements the plant structure.

The composition of hemicellulose and lignin as well as the proportion between cellulose, hemicellulose, and lignin fractions is different for every type of green biomass. Table 7 summarizes the lignocellulosic composition of different woody and herbaceous feedstocks. According to this, wood shows a higher lignin content than herbaceous biomass. Especially coniferous wood, often referred to as softwood, features a lignin content of about 30 wt.% on a dry basis.

The thermal decomposition of biomass is controlled by the chemical composition of its major components. Pyrolysis of these materials proceeds through a series of concurrent and consecutive reactions [39]. Each component reacts at different rates and by specific pathways. The rate and extent of degradation of each of these components depends mainly on temperature, particle size, and time of exposure.

Biofuels: Upgraded New Solids. Table 7 Composition of different biomass types [39–41, 43]

	Cellulose (wt.%)	Hemicellulose (wt.%)	Lignin (wt.%)
Woody biomass, dry basis

Bagasse	38	39	20

According to Fig. 3 five temperature regimes for the pyrolytical decomposition of biomass in the low temperature range up to 300°C can be distinguished.

- Temperature regime A represents the physical drying of the biomass.
- Regime B is only valid for lignin and is defined as a temperature zone in which softening of this biomass constituent occurs.
- Regime C is characterized by depolymerization and condensation of the then shortened polymers.
- Temperature regime D leads to limited devolatilization and carbonization of the intact polymers and the solid structures formed before.
- Regime E leads to extensive devolatilization and carbonization of the polymers as well as of the solid products that were formed in regime D.

Figure 3 illustrates the different temperature regimes for each class of biopolymers. The blue line splits the torrefaction zone in a low and high temperature regime. Hemicellulose decomposition starts at lower temperatures and proceeds over a narrower temperature range as compared to cellulose and lignin. It is responsible for the main devolatilization in the torrefaction temperature regime of less than 250°C. Thereby, the reactivity of hemicellulose is depended on its specific composition. A significant difference between the decomposition of hemicellulose of coniferous and deciduous wood can be observed [42]. The latter consists predominantly of xylan-based hemicellulose, which is much more reactive and exhibits a higher degree of carbonization as compared to coniferous wood. Lignin and cellulose do not make a substantial contribution to mass loss so far, but their structure experiences chemical changes. Depolymerization reactions lead to a fragmentation and softening of the cell wall skeleton. The result is a better grindability of the torrefied biomass as compared to the raw material.

Above 250°C, both lignin and cellulose start to decompose while decomposition of hemicellulose gets extensive. A variety of permanent gases and condensable liquids is formed. The main gaseous species are carbon monoxide, carbon dioxide, water, and acetic acid. The reaction products remove part of both (i.e., the initial mass and the chemical energy represented by the organic part of the biomass). The decomposition

Biofuels: Upgraded New Solids. Figure 3

Temperature regimes for the low temperature pyrolytic decomposition of cellulose, hemicellulose and lignin (Taken from [42])

process is considerably faster at high temperatures. Decomposition is not completed within typical process residence times. Hence, higher temperatures as well as longer residence time cause lower mass yields but the remaining solids have different properties.

A main part of the available research work published so far concentrates on the influence of process parameters on the torrefaction of various biomass feedstocks under different conditions [1, 40, 43–48]. As the torrefaction characteristics in Fig. 4 indicate, reaction temperature and residence time are crucial for process design. Its choice faces a trade-off between: (1) high energy yields, required for good process efficiency; (2) substantial mass reduction, required for energy densification; and (3) high throughput, required for good process economics. The energy yields shown in Fig. 4 refer to the higher heating value (HHV)

of the wood briquettes, neglecting the benefits from wood drying. Even so, the energy yield of torrefaction is always higher than the mass yield. Both higher reaction temperature and longer residence times cause a more pronounced biomass decomposition. Higher temperatures lead to greater differences between energy and mass yield as compared to longer residence times. With respect to process economics, it is advantageous to adjust the reaction temperature above 250°C, allowing for residence times of less than 30 min.

Particularly, the effect of the reaction temperature has been examined since it is the most influencing parameter on process yield and product properties. Figure 5 summarizes experimental results for different types of biomass. The acceleration of mass losses for reaction temperatures above 250°C is in good agreement with the temperature regime model.

Properties of Torrefied Biomass

Torrefied biomass can be classified as an intermediate product between raw biomass and charcoal [44]. By adjusting temperature and process time, it is possible to make the product more or less similar to charcoal.

The net calorific value (LHV) of torrefied biomass is in the range from 18 to 22 MJ/kg for herbaceous biomass and 20–24 MJ/kg for wood. Energy density is a factor of 1.2–1.3 higher compared to the raw biomass on a dry basis. Figure 6 shows that energy densification is related to an increase of the elemental carbon fraction, accompanied by a decrease of the molecular H/C and O/C ratios (Fig. 7), which is favorable for further utilization since less water vapor is formed, improving energy efficiency.

The equilibrium moisture of torrefied biomass is around 3% (i.e., roughly three times less than the equilibrium moisture of the raw materials). Two reasons for the low water uptake are proposed: (1) tar condensation inside the pores, obstructing the passage through the solid, and (2) the nonpolar character of condensed tar on the solid, also preventing the condensation of water vapor inside the pores [44]. Hence, transportation and storage of torrefied biomass are easier as compared to the raw material.

Usually, torrefied biomass is milled and pressed to form briquettes or pellets in order to enhance the handling properties. From the gasification point of view, a solid biofuel should be homogenous in chemical composition and size. Especially entrained-flow gasification asks for small particle sizes of less than 1 mm. Size reduction experiments have been performed with untreated and torrefied biomass in order to determine the power consumption of a cutting mill [40]. According to this, power consumption is greatly reduced when the biomass is torrefied. A reduction of maximal 85% has been measured (i.e., the electricity required for grinding torrefied biomass consumes only 1.5% of the biofuel energy content (assuming 40% power generation efficiency) as compared to 12–16% in case of untreated biomass). In these experiments, the mill capacity for torrefied wood was up to 6.5 times the capacity of untreated wood. Additionally, particle size distribution and shape is more uniform for torrefied wood.

The improvements of the grinding properties are caused equally by physical and chemical changes [40]. The chemical changes responsible for this behavior occur relatively fast and in the first stages of decomposition (temperature regimes C and D in Fig. 3). Hence, reaction temperatures above 250°C and residence times of >10 min hardly will bring further improvements.

Torrefaction Plants

Torrefaction plants integrate several mechanical and thermal processes (i.e., chopping, drying, torrefaction, cooling, milling, and compaction). If the process aims to produce a commodity fuel as shown in Fig. 8. Compaction usually means pelletizing of the torrefied biomass since this kind of packing provides the best storage and transportation properties.

The first commercial-scale torrefaction plant was built in the frame of an EC Demonstration project in 1987 in France [37]. The plant has been operated with forestry wood. The capacity has been 12,000 t of torrefied wood per year. The product was mainly used as a coke substitute in electrometallurgy and some was sold as barbecue fuel. The plant has been decommissioned in the early 1990s for economic reasons [42].

This so-called Pechiney process [37] was based on an indirectly heated screw reactor. The process consisted of three main sections: chopping, drying, and torrefaction. Figure 9 gives an overview of the different basic process units and their interconnection.

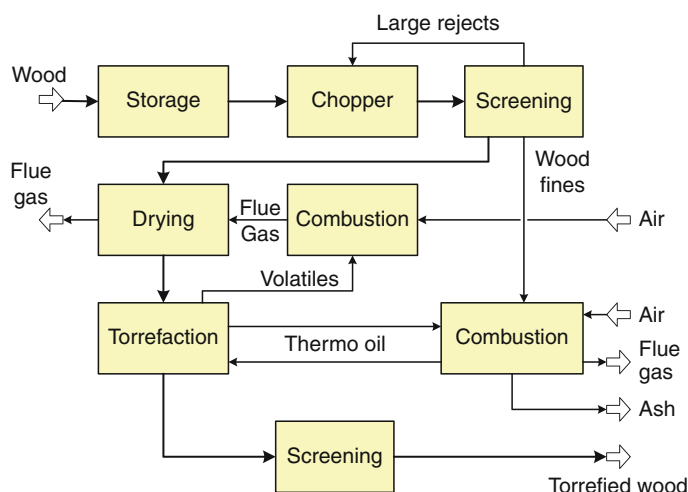

Forestral wood with typically 40% moisture content was first chopped and screened. The wood fines were burned to supply heat to thermo oil circulating between the torrefaction reactor and the boiler. The remaining wood chips were dried to 10% moisture content before being fed into the torrefaction reactor. Hot air from the combustion of the torrefaction gas was used for this purpose.

The reactor was developed as a post-dryer for solids requiring homogeneous product moisture content. The size of that kind of reactor is typically determined by the heat duty, as the area for heat exchange is limiting. Higher feed moisture contents lower the reactor throughput capacity. Temperature control of the reactor is easy because of the limited heat transfer rates that are responsible for a limited capacity and long residence times of more than an hour. The result is a comparatively expensive process

Biofuels: Upgraded New Solids. Figure 8

Process steps of a torrefaction plant

Biofuels: Upgraded New Solids. Figure 9

Flow sheet of the Pechiney torrefaction plant in France according to [42]

with production costs of roughly 100 €/t without feedstock costs [42].

The energy efficiency is in a range of 65–75% including feedstock and utility usage. Serious energy losses occur due to fines production during cutting and sieving of the biomass feedstock [42].

With the beginning of the twenty-first century other applications renewed the interest in torrefied wood. Worldwide, different companies announced plans for the construction of torrefaction plants on an industrial scale of some 10,000 t/a. They address the market of low-carbon fuels for decentralized cogeneration and co-firing in coal combustion and gasification plants. Most of the plants should not mainly supply a single recipient but produce a marketable biofuel suitable for different industrial applications.

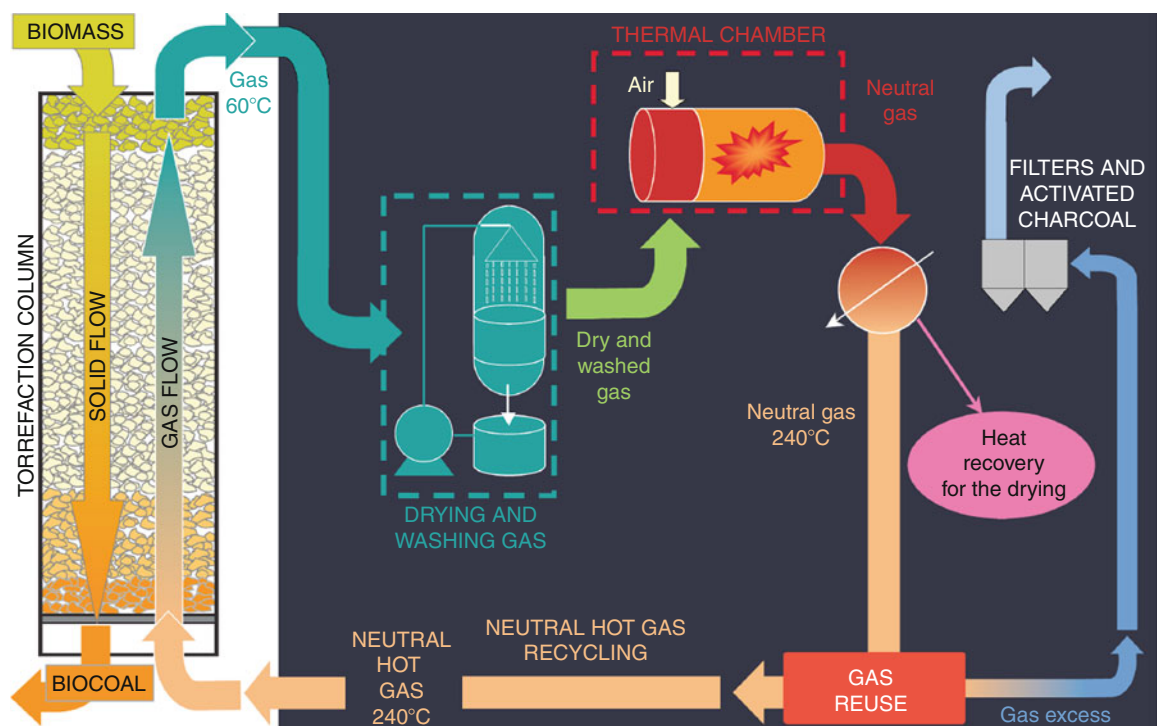

Recently announced torrefaction plants rely on direct heat transfer. Most of the suppliers utilize rotating drums or circular trays which origin from drying technology. Others operate with a moving or fluid bed (Fig. 10). Direct heat transfer is usually realized by conducting the hot flue gas from the combustion of the torrefaction gases through the reactor, but some concepts operate with circulating inert gas reheated by heat exchanger. In that case, heat is generated by burning the torrefaction gases and some additional wood fuel.

Hydrothermal Carbonization

Although the scientific investigation of hydrothermal transformation of biomass is ongoing for decades, efforts of technical applications are quite young. Therefore a brief historic overview of hydrothermal carbonization is given.

In 1913, Bergius described the hydrothermal transformation of biomass into a coal-like product as one result of his investigations of the natural coal genesis [51]. In the 1920s and 1930s this investigations were continued and extended. These results have been confirmed in new test series in the 1960s. Around 1995 various companies started with the development of a process for the use of waste biomass (like sewage sludge) and for decontamination and disinfection. Based on this, the SlurryCarb™-process was developed as the first ever commercial process for the hydrothermal production of a coal-like product out of organic waste. Several laboratory and demonstration plants have been built and tested since 1997. In 2008, a first commercial pilot-plant started operation in Rialto, USA. It converts 900 t of biomass per day.

Besides solid biomass with limited water content usually converted thermochemically, there is a certain potential of wet biomass available (like manure, food industry wastes, digestates from biogas processes,

Biofuels: Upgraded New Solids. Figure 10

Torrefaction process using a moving bed reactor (Source: Thermya)

sewage sludge, and black liquor) [52]. The necessary drying obstructs the use of these kinds of feedstock in classical thermochemical processes. In case of wet biomass with 20–30% dry organic matter, the heat generated by the combustion of the organics has the same amount as the heat needed for the vaporization of the water. Therefore, wet biomass should be converted in processes without a need for preliminarily drying.

Mainly two processes fulfill this requirement for wet biomasses: biogas production and hydrothermal conversion. In the biogas process, wet biomass is biochemically converted into a methane-rich gas. However, mainly carbon hydrates are usable and the lignin remains unconverted due to biological constraints. This means, that the energy of the lignin cannot be used. Additionally, there are organic materials like straw, which can hardly be solubilized in the biogas process. In contrast, hydrothermal processes are able to convert all organic fractions.

Common hydrothermal processes are hydrothermal carbonization (HTC), hydrothermal gasification, and hydrothermal liquefaction also known as hydrothermal

upgrading (HTU) [53–57]. Since the main product is a solid, only hydrothermal carbonization is tackled within the following explanations.

Principles

The properties of water at enhanced temperature and pressure may vary from those of cold water [57–59]. Above the critical point – characterized by 375°C and 221 bar – water is able to dissolve silicon dioxide and fat. At these conditions, basic properties of water change (e.g., the dielectric coefficient, the ion product) [60, 61].

During hydrothermal carbonization, the organic material is preheated. Due to this thermal energy, the macromolecules in the biomass are degraded and smaller molecules are formed out of them [62]. The pH-value mainly influences what kind of compounds is degraded. While carbohydrates can be decomposed under sour conditions, lignin degradation asks for a high pH-value. Favorably it will be converted into phenols while aldehydes and furfurals will be produced

from the decomposition of cellulose and hemicellulose [63–65]. Starting with these smaller molecules, new larger compounds are built. In these reactions, water is eliminated. Reaction mechanisms of hydrolysis, dehydration, decarboxylation, aromatization, and condensation polymerization are involved in the conversion of biomass into biocoal [66].

The new substances formed after the partial degradation of the macromolecules have properties like humic substance or lignite. For energy applications, the target has a lignite-like quality. In contrast to pyrolysis coke, which in principal consists of carbon, the product of the hydrothermal carbonization (so-called biocoal) is characterized by the elemental formula C_6H_2O .

Hydrothermal carbonization covers two different processes, the classical hydrothermal carbonization and the SlurryCarb™-process. The former uses mild reaction conditions of 170–250°C and 10–20 bar. A catalyst (e.g., citric acid, ferric sulfate) is necessary. Catalysts allowing to lower reaction temperature or residence time are a major target of fundamental research. At present, the operating conditions have to be applied for 3.5–16 h. This very long residence time is a weak point of the entire process.

The SlurryCarb™-process operates at 220–270°C and up to 220 bar. It needs only 10–60 min for the carbonization [67, 68]. However, high-pressure reactors are required. Additionally, above a reaction temperature of 240°C the phenol load of the wastewater increases strongly [69].

Energy Balance The hydrothermal carbonization is an exothermal process. Therewith, the process may proceed without an external heat supply. But the energy converted from chemical energy into heat is not contained as usable chemical energy in the product any more. This heat generation can amount of up to 30% of the energy contained originally within the feedstock. Thus, the energetic efficiency of the conversion process of biomass into biocoal is between 70% and 90% [67, 70].

For the operation of the hydrothermal carbonization, it is necessary that the biomass particles are surrounded by water. Otherwise, the reactions cannot occur regularly. Usually, HTC reactors require a pumpable or pasty feedstock. The minimum water content for such properties differs depending on the

other characteristics of the biomass. Typically, a water-to-dry-matter ratio of 2:1 is necessary. In that case, one-half of the generated heat is needed for preheating the feedstock. Furthermore, the biocoal and the water do not separate themselves. After a mechanical water separation by filtering or centrifugation, an additional thermal drying is necessary to provide an energy carrier from the biocoal. For the efficiency of mechanical separation, first results are available [71]. As a result, after 2.5–5 min in action, water content in biocoal of 30–45% is reached. With centrifugation after SlurryCarb™-process, 50% water in the product is achievable [68].

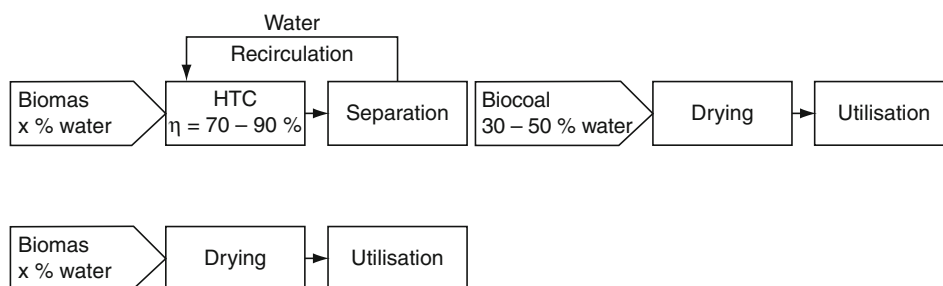

Of course, the heat for feedstock preheating and drying is partially regenerable. But, considering the technical possibilities of heat transfer, characterized by the necessary temperature differences and the heat losses, hardly any heat for external use will remain.

All over, the energetic efficiency of the hydrothermal carbonization depends on the water-content of the raw material and how easy it can be dewatered mechanically.

Figure 11 compares brief process chains of biomass utilization, for example, combustion with and without hydrothermal carbonization.

Waste Water Until now, several questions of the hydrothermal carbonization are not clarified comprehensively. One of the most important open questions is the wastewater treatment. Different types of water pollutants have been identified (i.e., inorganic as well as organic substances). The water-soluble inorganic substances available in the feedstock will be dissolved. This affects both, the minerals typical for biomass (like ash components, nutrients) and the inorganic feedstock pollutants (like heavy metals). In this case, water pollution corresponds with a decontamination of the solid phase. The leaching of ash components can upgrade the combustion behavior.

Organic substances in wastewater can have two sources. The first source is water-soluble organic compounds preliminarily available in the feedstock. Those of these compounds not degradable under the conditions of hydrothermal carbonization could be dissolved in the process water. Additionally, substances formed in the hydrolysis process and not consumed during the new forming of large compounds can remain in process water. Typically, different kinds of

Biofuels: Upgraded New Solids. Figure 11

Process chains for the utilization of biomass with and without hydrothermal carbonization

Biofuels: Upgraded New Solids. Table 8 HTC waste water ingredients [71]

Parameter	Value
pH-value	3.7–7.2
Biochemical oxygen demand (BOD)	10,000–42,000 mg/L
Chemical oxygen demand (COD)	24,200–68,500 mg/L
Total organic carbon (TOC)	9,000–36,100 mg/L
Nitrate-nitrogen	2.9–58 mg/L
Ammonia-nitrogen	3.4–4.1 mg/L
Phosphate- phosphor	0.2–47 mg/L

phenol-like substances can be found in the wastewater. The chemical oxygen demand is correspondingly high. Typical amounts of wastewater ingredients are listed in Table 8.

Phthalates, pyrazines, phenols, other oxygen containing cyclic compounds, and aliphatic and aromatic hydrocarbons mainly represent the content of organic substances [71].

Apart from wastewater recycling, different water purification processes are possible. The content of organic pollutants, represented by chemical oxygen demand (COD), can be decreased by 90% within a biogas plant (i.e., anaerobic treatment). Downstream, a final cleaning can be done with activated carbon [71]. Often discussed is integration with a biogas plant in a manner that the HTC plant uses the digestates and the biogas plant uses wastewater from the HTC.

The flue gas of the HTC process contains less than 5% methane and more than 90% carbon dioxide with low amounts of hydrogen, oxygen, and hydrogen sulfide [72].

Hydrothermal Carbonization Processes

Currently, the transformation from laboratory scale to technical plants is ongoing. Therefore, the state of technology outlined below might change rapidly.

The reaction temperature and pressure of the hydrothermal carbonization are easy to handle with available process technology. The core question of the commercialization of the HTC process is the residence time. For example, for a resistant time of 12 h and a fuel output (dry matter) of 10 MW a reactor volume of 50–100 m³ will be necessary to the discussed feedstock water contents. For the use of mechanical dewatered sewage sludge with the typical water content [73], the necessary reactor size for about 35 bar can increase up to 250 m³. This is why the reduction of resistant time is crucial for the successful technical implementation. The SlurryCarb™-process with decreased residence times of minimum 10 min [74] is in this case is advantageous. But, because of the described problems with the wastewater quality, the resistant time reduction must be reached by advanced catalysts for the future.

The long residence time causes the use of several reactor types. Tube reactors and discontinuous reactors allow for the control of the residence time. Because of the necessary size of the reactors, uncommon designs (like sub-terrestrial pressure vessels) are discussed.

The SlurryCarb™-process is the only process realized in a larger pilot plant. This plant converts 900 t of

sewage sludge a day to 170 t of solid fuel [68]. For every other process, the construction of a demo plant or pilot plant is ongoing.

Biocoal Properties

The properties of biocoal depend on the reaction conditions. With increasing residence time, the product changes its manner from humus like to lignite like. Analysis values are listed in Table 9. General combustion properties are given in Table 10.

These chemical analysis values, especially the heating values and the contents of carbon, hydrogen, oxygen, nitrogen, and sulfur, show that biocoal can be used in energetic applications.

The biocoal is described to be a lignite substitute. Many chemical properties are in fact quite similar to lignite. But, it has to be seriously observed, that at least one of the main combustion properties, the content of volatile matter, differs completely. This parameter of HTC-biocoal is rather in a range typical for green

biomasses. Because the ignitability and the properties of the flame are substantially determined by the content of volatile matter, the combustion of HTC-biocoal cannot be similar to lignite combustion. Instead of that, the combustion behavior will be between green biomass and lignite. Future research has to show which kind of combustion technology, either lignite technology or biomass technology, is able to utilize HTC-biocoal most efficiently.

The solid product has a macroscopic particulate shape or the shape of the feedstock particles remains. Only the physical and chemical properties change and the particles get a fissured and porous structure. Thus, the fibrous structure of the green biomass is destroyed. The biocoal is a highly functionalized carbonaceous material [77] microscopic composed of agglomerates of microspheres. This means that the biocoal is neither in the chemical surface properties nor in the microstructure, similar to pyrolysis coal with little functional groups at surface and also with a porous structure characterized by lots of micro-channels.

Biofuels: Upgraded New Solids. Table 9 Elementary analysis and heating value of biocoals from HTC compared with its biomass feedstock (dry matter) [75]

Feedstock	Condition	Elementary analysis					Heating value (LHV) (MJ/kg)
		C (%)	H (%)	N (%)	S (%)	Ash (%)	
bark mulch	green	45.5	6.1	0.6		5.8	18.7
	HTC-biocoal	55.7	5.8	0.6		6.8	22.1
leaves	green	45.3	6.8	1.1	0.02	11.1	18.1
	HTC-biocoal	56.4	6.1	1.1	0.01	11.7	24.2

Biofuels: Upgraded New Solids. Table 10 Combustion properties of biocoal from HTC compared with brown coal and biomass (dry matter) [1, 76]

	HTC-biocoal	Brown coal (Rhineland)	Brown coal (Lusatia)	Softwood (spruce)	Straw (wheat)
Water content (%)	8	11	10.5	15–20	10–20
Ash content (%)	1.5	4	6	0.6	5.7
Volatile matter (%)	74.5	46	45.5	82.9	77.0
Sulfur content (%)	0.2	0.4	0.8	0.02	0.08
Heating value (LHV) (MJ/kg)	20	22.2	21	18.8	17.2
Ash softening temperature (°C)	≈1,200	>1,100	>1,200	>1,400	<1,000

Other crucial properties for the applicability of the biocoal are the water content and in connection with this the consistency. Depending on the water content of the feedstock, the biocoal occurs as a suspension. Because of this, the water cannot be removed only with mechanical processes up to a content which make utilization in a classical thermochemical process (like combustion or gasification) possible. That is why an energetic reasonable application of the hydrothermal carbonization requires also an answer to the question of water removal.

In the contrary, the products of hydrothermal gasification and hydrothermal upgrading can be extracted from water by phase separation processes, which cause hardly any energy demand.

Biocoal Applications

The use of biocoal in lignite application processes is one option. Because of the analogy of some of the fuel properties, biocoal may substitute lignite in different fields of use. Such a substitution saves greenhouse gas emissions, which is important for the climate protection and governmentally funded in many countries.

Because the content of volatile matter of HTC-biocoal is similar to biomass and its heating value is high in comparison with biomass, pellets from biocoal (or with a percentage of biocoal) might be an important addition for the pellet markets of the future. Uses for coal sludge are currently in a research stage. They can avoid the energy demand for drying. Gasification and combustion of coal-slurries are state of the art, but in this case the energy demand is only removed into the gasifier or furnace.

In general, the solid fuel produced by hydrothermal carbonization requires a complex conversion process for solid fuels. In most cases, gaseous or liquid products will be easier to apply.

Apart from the energetic application, the use of biocoal from HTC for the fertilization of soil and carbon sequestration is intensively discussed. Here, biocoal is mixed into topsoil. But, the advantages (e.g., increase of fertility and stability of the carbon disposal) to be achieved in practice are currently not clarified [78].

Biocoal has hardly any analogy with activated carbon or carbon black. That is why biocoal cannot

be expected to be a substitution for these. Nevertheless, there are serious activities for the production of engineering carbon materials via hydrothermal carbonization [79].

Summary and Future Directions

Each of the discussed processes provides an important possibility for the production of high value solid biofuels. The main process characteristics are:

- Pelletizing and briquetting are physical processes; torrefaction and hydrothermal carbonization also influence the chemical structure and the chemical behavior of the fuel.
- Pelletizing, briquetting, and torrefaction occur in a gaseous atmosphere while hydrothermal carbonization runs in hot pressurized water
- Pelletizing, briquetting, and torrefaction require dry feedstock; hydrothermal carbonization has the greatest advantages for wet biomass.

Because of the different process characteristics, these processes have their own specific future directions and potential impacts on the development of certain areas of science.

For the further development of solid biofuels, produced by pelletizing and briquetting, the compaction process needs to be understood in depth to adjust the process parameters in an optimal way. Therefore, the interactions of the parameters influencing the process and their influence on the resulting properties of the compacts have to be figured out. Important questions are, for example, the influence of particle size distribution and the water content of the raw material on the mechanical durability of the compact or the optimal compaction pressure needed for a certain compact strength and the possibilities to influence it by conditioning or by adding binding agents. Besides the adjustment of optimal compact properties, the knowledge of these correlations allows the optimization of the process itself and of the energy efficiency which directly affects the costs of the biofuel production. Therewith the goal is the simulation of these processes for better understanding and for an optimal compaction of the raw materials.

The benefits of pelletizing and briquetting processes are (1) a higher durability because of reduced water

content and (2) a higher volumetric energy density. Furthermore, admixtures compensate variations. Nevertheless, there is no substantial change in the chemical composition during the pelletizing and briquetting processes [18, 80, 81, 83].

Torrefaction process technologies have reached a commercial scale. The process technologies are derived from drying technology. The major drawback is a comparatively long residence time of some 10 min resulting in large reactors with high investment costs. Process economics and the development of a sufficient market for torrefied biomass pellets is still an open question, but recent investment decisions indicate good market opportunities.

The torrefaction product is a highly reactive solid biofuel with good combustion properties. Torrefied biomass pellets are suitable for biomass combustion and gasification plants as well as for co-combustion and co-gasification plants.

The main question for the future of hydrothermal carbonization is for which feedstock and for which process chains an energetic, economic, and environmental benefit can be reached. Therefore, a lot of balancing and assessment work has to be done. Open questions in addition are: (a) decreasing of residence time and (b) equipment optimization for biocoal production (i.e., water recycling, removal of inorganic pollutants, search for high toxic organic components, removal for wastewater treatment, and combustion, as well as pelletizing behavior for energetic use).

In general, the possibility of thermochemical use of wet biomass is an important chance. But, the question not answered until today is whether hydrothermal carbonization is the best alternative compared with other hydrothermal processes and the biogas process. According to the fuel characteristics and the economic conditions, each of the three described technologies could find its special use for energy production in the future.

Glossary

Biogas Biogas is a gas which is produced as waste product during anaerobic microbiological breakdown of organic substances. The main constituents are methane and carbon dioxide.

Biogas cleaning Biogas cleaning is a technical process which adapts the biogas quality to a defined gas quality defined by the subsequent usage. That includes mainly the reduction of trace gases (H₂S, NH₃, water vapor, and others). Biogas cleaning does not focus on the removal of carbon dioxide from the biogas.

CHP unit Combined Heat and Power unit which consists of a gas-burning engine driving a generator which produces electricity. The waste heat from electricity production can be used for further applications.

Landfill gas Landfill gas is a special type of biogas which is produced in landfills during the degradation of the organic constituents of wastes. It is characterized by many organic long-chain trace gases.

Sewage sludge gas Sewage sludge gas is a special type of biogas produced within wastewater treatment plants during the anaerobic treatment of sewage sludge. It is characterized by the content of siloxanes.

Definition of the Subject

This entry focuses on the development, its reasons, and the perspectives of the electricity supply based on biogas through anaerobic digestion. This sector is worldwide very important for decentralized energy supply from organic materials. Beneath this fact, electricity from biogas reduces the demand for fossil fuels and reduces greenhouse gas emissions connected with fossil-energy supply systems. Thus the development of this sector is analyzed. Based on this, the possibilities and the challenges of electricity supply from biogas and its contribution to reach national and international renewable electricity targets is discussed.

Introduction

Biogas can be produced from a very broad variety of organic substrates. Internationally, the main biomass sources are wastewater treatment sludge (to produce sewage sludge gas) and organic wastes from agriculture (e.g., excrements from animal farming, residues from processing of agricultural products). Additionally, high importance has to be paid to landfill gas production and utilization. In some countries as, e.g., Austria and Germany, the use of energy crops contributes additionally significantly to biogas production [10, 11].

Due to the fact that all these different kinds of biogases consist of roughly 50–70% of methane, the gas can be used easily as a fuel. In the past, very different engines have been developed to produce electricity from cleaned biogas. Parallel to these technologies, biogas can be used for cooking purposes, for heating, as well as a fuel for vehicles. But the latter is not a topic of this article.

History

The history of biogas production is already very long – especially for small-scale applications. Some very old experiences are recorded already from China and Persia. In industrial large scale, the first biogas plants were constructed for the purpose of wastewater cleaning. About 1897, at a hospital in Bombay, India, the first plant was constructed where the gas was used for lightening the streets, and from 1907 for the operation of a motor to run an electricity generator. After this beginning, more and more anaerobic wastewater treatment plants mainly in Europe were constructed and equipped partly with generators [1].

Due to the relatively high costs of electricity production from biogas, the gas was mainly used for heating and lightening, as well as a fuel for transportation purpose. But also, some enthusiastic farmers started between 1980 and 1990 with the construction of digesters and electricity generators with electrical capacities mainly below 20 kW based mainly on animal excrements. The electricity was produced to cover the own electricity demand within their farm.

With the implementation of feed-in laws for electricity into the national electricity grid, the technology

got incentives, and a continuous growth of the use as well as the plant size began [2].

For example in Germany, based on the incentives introduced in 1999, the electricity production from biogas increased rapidly. Especially financial incentives for the production of electricity from energy crops–based biogas lead to the very strong development (Fig. 1) especially in this area.

Within Europe, about 3,000 MW electrical capacities based on biogas (including landfill gas and sewage sludge) have been installed in 2007. Only Germany contributes with about 50% to this number [4]. Compared to the international situation, Europe dominates the electricity production from biogas [5].

Looking into the future, it is estimated, for example, for Germany that in the year 2050 a total capacity of electricity production from biogas of about 11,000 MW can be reached. Worldwide, the capacity in 2050 is estimated to reach about 100,000 GW [5]. Thus a very rapid growth of this sector is expected worldwide.

Technology

After some cleaning processes, biogas shows very good combustion properties. This is also true for the use in

Biogas for Electricity Generation, Hi-tech Applications. Figure 1

Development of electricity production from biogas (without landfill gas and sewage sludge gas) exemplarily for Germany [3]

engines. For that reason the use of biogas for electricity supply has a long tradition. Thus, there are lots of experiences available and the obstacles for electricity supply from biogas under very different conditions are very well known. This is analyzed within the following chapters.

Biogas Production

Biogas is produced mainly from organic residues and wastes. Such organic matter can result from animal breeding (excrements), crop production (harvest residues), processing of agricultural products (residues from beer brewing, vegetables processing, beverage industry, and others), organic municipal or industrial wastes, organics in wastewater streams, wastewater cleaning processes, and many other sources. Energy crops are another (costly) biomass resource for biogas production which are actually only used in some countries. The question if a biomass source can be used for biogas production is answered by its anaerobic degradability.

Biogas production is a microbiological process taking place under anaerobic conditions (at total exclusion of oxygen). The microorganisms involved into this process are omnipresent but concentrated in anaerobic sources as, for example, the stomach of ruminants. For applications with the aim of biogas production, the ruminant's stomach has more or less to be emulated so that the process is mainly carried out in so-called fermenters which are gastight and mainly equipped with some stirring devices. Very simple household digesters which supply cooking gas, e.g., for families in rural areas of developing countries as well as industrial-scale solid substrate digesters (garage-type), are constructed without stirring devices. They show often comparably low gas yields. Therefore, most industrial applications realize some movement within the fermenter (Fig. 2).

The choice of the fermenter type depends mainly on the substrates. But also, the economic-frame conditions as well as the chosen installation company have a considerable influence. Therefore, a broad variety of technologies can be found on the market.

The dimension of the fermenter depends on the amount of biomass to be treated and the biological dimensioning to avoid an overload of the microbiological

community. It also plays an important role if a one-staged or more-staged process is realized. So far, single fermenters with dimensions between 20 and 8,000 m³ can be found on the market. Typical fermenters used, e.g., in Germany, for agricultural biogas plants are sized between 1,000 and 2,500 m³. Biogas amounts of 2.5–500 m³/h are produced which are equivalent with about 5–1,000 kW electrical capacity of a gas engine. For larger plants (the largest known is 10,000 m³/h biogas production at one single place), two or more fermenters are connected or placed parallel.

Much attention has to be paid on the right temperature for the fermentation process. Active bacteria do not tolerate fast changes in temperature resulting in a reduced efficiency and in lower degradation rates within the fermenter. Thus, the temperature in the fermenter should be constant and changes should not exceed 2 K/week. For this reason, heating systems in industrial scale fermenters should be designed carefully.

Internal fermenter heating systems can be designed in various ways. One option is that stainless steel heat pipes are installed within the fermenter some centimeters away from the fermenter walls. Another possibility is that they are embedded within the concrete walls and the concrete bottom. The heat exchange rates are much higher when the pipes are not installed within the concrete, but the heat exchanger rate may be reduced due to dirt attachments at the pipes fixed within the fermenter. Additionally, technical stirrer faults can cause demolition of the pipes. Heat pipes at the fermenter bottom cannot be suggested because almost all biogas plants show sedimentation of material within the fermenter, reducing the heat exchange significantly.

External heating in heat exchangers is realized in cases where a continuous circulation of the fermenter content is technically necessary. If this is not the case, external heating requires additional electrical energy for a circulation pump. The advantage is that only external heating allows a regular cleaning of the heat exchanger surface.

All fermenters – except the garage-type fermenters – require movement of the substrate through any type of pipe.

Substrates with very high content of solids (20% and more) can be transported in screw conveyors.

Biogas for Electricity Generation, Hi-tech Applications. Figure 2
Overview on the main types of industrial fermenters with stirring [6]

Due to high abrasion, screws and walls have to be constructed very robust preferably from stainless steel. Very positive effects on continuous operation and low maintenance show applications of walls which can be removed easily in two parts and which can be adjusted depending on the abrasion of the screw (the diameter will slightly decrease). Stones and solid parts have to be removed from the substrates before passing screw surveyors.

Substrates with a lower content of solids are transported in pipes mainly. They are moved by

pumps. Special requirements on the pumps result from substrates with 5–20% solids content. In these cases, best experiences are reported from the use of rotating piston pumps and eccentric screw pumps, which can be found on almost every agricultural and industrial biogas plant nowadays. They are used for substrate supply to the fermenter as well as for transportation purposes between different fermenters and storage tanks. Only the removal of the digested slurry is not realized by a pump mostly. It is realized with an open siphon where the overflow from the fermenter

leaves due to gravity and due to processes of new substrates supply into the fermenter without additional energy demand. For this reason the fermenter will not be overfilled and maintain a constant filling level.

Operational experiences for the fermentation unit of a biogas plant are in most cases very good. Special attention has to be paid on the quality of the stirrers, the additional technical equipment, and the internal coating of the fermenters. The aggressive atmosphere within the fermenter (due to the formation of sulfuric acid) requires stainless steel or totally coated surfaces of steel and concrete, especially in the gas room under the roof of the fermenter. Fermenters are estimated with a technical lifetime of 20 years and more when they are constructed at high quality. But the technical equipment shows in most cases only technical lifetime of maximum 10 years [7].

Fermenters are able to produce biogas all year round. Practical experiences show that it has to be expected that due to biological or technical problems, the fermenter has to be opened about each 3 years. For example, a removal of a sand layer, the exchange of the stirring system, or some maintenance work has to be done. Then it has to be calculated that the fermenter is out of operation for 1–4 four weeks, and thereafter a new start of the plant is necessary which leads to a startup phase with a reduced biogas production rate. Annually (without a real opening of the fermenter), a fermenter is available with roughly 95%. Due to biological process problems, it is possible that 5% of the year in average, not enough biogas can be produced to run the CHP plant at full load.

Electricity Production from Biogas

So far basically only motor-CHP units are used for electricity production. Additionally to a minor extent micro-gas turbines (worldwide probably about 100) are used. Almost independent on the device, the biogas has to be cleaned from H_2S , water vapor, and – dependent on the substrate – siloxanes.

H_2S , which can form sulfuric acid and increase corrosion effects, must be removed to levels between 150 and 400 ppm depending on the requirements of the supplier of the CHP unit. It is always suggested to go for a very low H_2S level in the gas to minimize maintenance work at the CHP unit and to prolong the

intervals for oil exchange; for example, levels of 100 ppm and below would result in notable reductions of maintenance cost which in many cases result finally in improved economic behavior of the overall biogas plant [7].

In many cases, with a low H_2S content, it could be sufficient to use the so-called internal biological sulfur-removal method. Here the H_2S content is reduced with sulfur-reducing bacteria (sulfobacter oxidants) living in the gas space of a fermenter. They convert H_2S into elementary sulfur which is then removed with the digested substrate. Such a sulfur-removal requires on the one hand sufficient area for settling of the bacteria (e.g., a layer of wood beams or nets) and, on the other hand, the continuous supply of some oxygen (about 3% to maximum 6% compared with the biogas production rate [8]).

For a higher H_2S content and/or improved reduction rates, additional equipment for external biological, physical, or chemical desulfurization is required. This can be [9]:

- External biological desulfurization, where within a washing column, a biological desulfurization as described above takes place under controlled conditions
- Biochemical washing, where the H_2S is bound in a first column chemically to, e.g., soda lye and is separated from that in a second column without bringing oxygen into the gas system
- Sulfide precipitation in the fermenter, where sulfide binding chemicals (Fe-III-chloride, Fe-II-chloride or Fe-II-sulfate) are given with the substrates into the fermenter
- Adsorption to activated charcoal, where in separate vessels, the raw gas is led through a packing of charcoal which allows the highest degree of gas cleaning

For water-vapor reduction in the gas phase, at least a condensation of water in the raw gas-pipe system has to be realized through piping the gas under the earth. For improved drying of the raw gas, the application of technical dryers is suggested. They have to be resistant against formation of sulfuric acid in the condensate. It has to be noted that the gas will be saturated with water at the temperature of fermentation, and notable condensate amounts have to be handled.

Siloxanes are relevant mainly for gases resulting from digestion of sewage sludge and municipal solid waste as well as from landfill gas. They can cause depositions of silicates in the engine. They could be the reason for massive technical problems. For reduction mainly, activated char coal filters can be used.

The different CHP-unit types do show differences in their technical performance and operational behavior. Mainly, it has to be distinguished between gas-otto-engine-driven CHP units, ignition-oil CHP units, and micro-gas turbines which are in practical and commercial use [9].

- Gas-otto-engines only use the biogas as fuel. They are operated with the otto-engine principle with air in excess and equipped with a turbocharger. The methane content in the biogas has to be above 45% (Table 1).
- Ignition-oil engines use the biogas, but always between 7% and 10% additional ignition oil (diesel, vegetable oil, biodiesel). The engines use the same principle as conventional diesel engines and are operated with air excess. In dependency of the gas quality and availability, the ignition oil share can be increased up to 100% so that not necessarily the engine has to be turned off during maintenance work at the biogas plant (Table 1).

- Micro-gas turbines only use biogas as fuel. They are fast-running gas turbines with a small electrical capacity (today max. 600 kW) with air preheating within a recuperator and a generator driven by the expanded gas after its combustion. The methane concentration in the fuel has to be above 35%, and the turbines tolerate higher H₂S concentrations than other CHP units. The high frequent noises can be quietened easily, and the waste heat can be delivered at a much higher level than from the other CHP units (Table 1).

From practical applications, it was measured that most plants do not run nonstop throughout the year due to maintenance but also due to faults and problems at the plant. For regular maintenance, about 150–200 h/year (less than 10 days) have to be calculated. Keeping that in mind and on condition that the fermenters continuously produce the full gas amount for full load of the CHP unit, it can be expected that the availability of the whole plant would be at 97%. Practically, gas production cannot run at exact 100% of the demand and should not waste gas what cannot be used in the CHP unit. Thus the gas production is mostly at about 95% or less in average compared with the capacity of the CHP unit. Therefore – as shown in Fig. 3 – in practice, most plants show a calculated standstill time

Biogas for Electricity Generation, Hi-tech Applications. Table 1 Comparison of the different types of CHP units; according to [7]

Parameter	Gas-otto engines	Ignition-oil engines	Micro-gas turbines
Capacities electrical	300 kW...3 MW	5 kW...500 kW	10 kW...600 kW
Electrical efficiency	35...43%	35...42%	21...33%
Thermal efficiency	40...44%	40...44%	50...60%
Heat-level water cooling/thermal oil	95/105 °C (50%)	95/105 °C (50%)	Overheated steam
Heat-level waste gas	300–400 °C	300–400 °C	300–600 °C (100%)
Lifetime	60,000 h	35,000 h	40,000 h
Emissions	NO _x and CO medium level	NO _x and CO at borders of legal limits	Very low
Special remarks	Engines designed for gas/biogas use	Highest electrical efficiency at low capacities; use of adapted standard diesel engines	Low noises

Biogas for Electricity Generation, Hi-tech Applications.

Figure 3

Theoretical cumulated standstill time of CHP units in practical agricultural biogas plants; the frequency is calculated as the share of really produced electrical energy of theoretically possible electrical energy production [7]

less than 60 days. The plants with longer standstill times in Fig. 3 had during the period of analysis notable biological problems, they were not full time in operation or they had any technical fault so that they should be excluded from evaluation.

Expected Developments

Starting from the state of the art described above and keeping in mind the strong research and development activities ongoing currently on an international level, it is expected that during the next 20 years, substantial improvements will be done.

Biogas production is a biotechnological process. But research activities just start with modern biotechnological methods. Therefore, within the years to come, new knowledge about the microbiological processes will be available which will lead to technical improvements so that it is expected that around 10% increase in the biogas yields could be realized. Additionally, the biogas plants will be better adapted to the substrates as well as the microbiological requirements. Also complicated or challenging substrates (like grass or straw) can be used in a more efficient way.

Regarding the electricity production process, it is expected that electrical efficiencies will slightly raise with about 2% in common CHP units. Fuel cells can find their way from demonstration activities into practice, what leads to significant higher electrical efficiencies

(45–60%). Other technologies are not expected to improve the overall behavior of decentralized electricity generation from biogas.

The overall plant behavior will show increased efficiencies in terms of reduced own heat and electricity demand, increased availabilities due to better knowledge on the processes, more applied measurement technologies, as well as more reliable technologies. Thus the expected full load hours are expected to rise to about 3–5%. At the same time, higher requirements regarding environmental impacts of biogas technology will lead to reduced direct and indirect emissions from today between 1% and 5% of the methane produced to a value lower than 1%.

Obstacles

There is no technology without obstacles. Technically it can be stated that biogas technology is well known, and biogas plants can be constructed and operated satisfactorily when suitable substrates are used. Obstacles result more from economic view interfering with the organizational/legal framework.

Thus the main question is the applicability of the electricity produced. For an economic successful operation, it is very important that the framework allows trading of heat and electricity to neighbors and feed in into national energy grids. Without these prerequisites, a biogas plant has to be designed for decentralized energy supply for a single company and then a balance between energy supply and energy demand has to be reached.

The second important question is if electricity production from biogas is economically viable. The production costs are often higher than local energy costs. This depends mainly on the costs for substrates and revenues for the products. The latter includes not only energy but also solid or liquid residues (i.e., digested slurry) which are a valuable fertilizer. Effects of reduction of greenhouse gas emissions and other environmental advantages should also be taken into account. Regarding the revenues for the electricity in many countries, very good experiences were gained with defined long-lasting guaranteed tariffs for each kWh fed in into an electricity grid.

Economics of Electricity from Biogas

The costs for electricity production from biogas depend on very many factors, mainly connected with substrate supply. Therefore only few examples are given from the German market of industrial biogas applications. Thus Table 2 shows the main cost positions for three different typical plant sizes and types.

Generally, the production costs of electricity from biogas are higher than 0.1 €/kWh, and so far higher than electricity production costs from fossil fuels in most cases (i.e., grid connected electricity generation in large-scale units). Only plant C shows lower costs, but this is caused by the very promising situation that the substrates are not connected with costs. If for some of the substrates paying would be necessary (and this is the case, e.g., for organic waste streams from food processing competing with fodder for animal

breeding), the production cost would rise above 0.1 €/kWh. This would also be the case for plant A when the vegetable residues would have been paid.

Thus there is the question if some further revenues could reduce the production costs. This could be the case if heat could be supplied and sold for a typical price between 0.02 and 0.035 €/kWh_{th}. Additionally, it could be the case that a farmer who uses the fertilizer can be convinced about the worth of the organic fertilizer and pays something for it. Last but not least, it is possible to generate revenues from acceptance of residues and wastes (e.g., from slaughterhouses), where the producer of the waste has to pay for to get rid of the waste material. But all in all, it is to assume that the influence of these revenues will never be more important than maximum 0.03 €/kWh_{el} production-cost reduction.

Biogas for Electricity Generation, Hi-tech Applications. Table 2 Typical cost assumptions for different typical German biogas plants

Parameter	Unit	Plant A	Plant B	Plant C
Capacity electrical	kWel	190	600	1,200
Electrical efficiency	%	38%	39%	40%
Substrates used	–	50% Manure, 20% grass, 30% vegetable residues	35% Manure, 65% energy crops	20% manure, 30% food production wastes, 30% slaughterhouse wastes, 20% used fats
Full load hours	h/a	7,500	7,700	7,700
Electricity production	kWh _{el} /a	1,425,000	4,620,000	9,240,000
Heat production	kWh _{el} /a	1,650,000	5,212,308	10,164,000
Specific investment costs	€/kW _{el}	4,500	3,500	3,000
Capital costs	€/a	98,325	241,500	414,000
Substrate costs	€/a	30,000	270,000	0
Maintenance costs	€/a	25,650	63,000	108,000
Operational costs	€/a	60,625	152,060	272,120
Residues transportation and use costs	€/a	18,000	36,000	60,000
Total annual costs	€/a	232,600	762,560	854,120
Specific electricity production costs	€/kWh _{el}	0,163	0,165	0,092

Thus for making the biogas production and use for electricity generation economically viable from an investors' point of view, financial incentives are necessary. This is especially true if energy crops – offering the largest potential today – shall be used.

Future Directions

Today, electricity from biogas has in many countries settled as a promising renewable electricity supply technology.

Thus it is expected that worldwide the biogas production as well as the electricity production from biogas will continue to grow in the future. Considering the significant expectable improvements in overall efficiency and environmental behavior of biogas plants, the technology seems one of the most promising among the possibilities of sustainable energy supply.

In the future, with increasing fossil-fuel prices and optimized technologies for biogas production and use, the production costs will converge at the level of fossil-energy prices. So in 10 or 20 years, electricity from biogas might be able to compete at the market commercially.

Glossary

Soil texture Describes the composition of the soil with regard to the proportion of the different grain size fractions of the mineral constituents. By adhesion forces in the varying pore sizes, the soil texture determines to a large extent the water storage capacity of soils as well as the capillary rise of water from deeper soil levels.

Effective root zone Soil depth, from which annual field crops can take up water by their rooting system. It is determined by soil texture as well as weather conditions.

Evapotranspiration coefficient (TC/ETC) The TC is a measure for the amount of water transpired by a plant stand for the production of a unit of plant matter (liters per kg DM), that is the reciprocal value of the water use efficiency (WUE). In addition to the transpiration, the water release of a plant stand is largely determined by the evaporation of the soil. Both processes are subsumed under the term “evapotranspiration,” which can then accordingly be described by the evapotranspiration coefficient (ETC).

Field capacity The field capacity describes the amount of water in the pores of a water-saturated soil that can be held against gravity after a period of more than 3 days.

Vernalization Induction of stem elongation/development of main shoot and generative phase by the impact of cold temperatures. Vernalization need of plants, e.g., winter cereals, prevents their blooming before winter.

Water use efficiency (WUE) Measure for the amount of plant matter produced for a unit of water transpired. It is equal to the reciprocal value of the transpiration coefficient.

Crop rotation Temporal succession of crops on one site.

Second crop Crop that is grown after a winter intercrop.

Intercrop Crop grown between the cropping of two main crops. Differentiations can be made between summer intercrops (main mass production before winter) and winter intercrops (main mass production after winter dormancy).

DM/oDM – (organic) dry matter Dry matter refers to the harvested biomass after exclusion of the water, which is part of the fresh matter. For a specification of biogas yields, organic dry matter is given as a reference value, which makes a subtraction of inorganic ash fractions from dry matter values necessary.

Mycotoxin Toxins formed by mold fungi, which are toxic to humans and animals. Most important

mycotoxins in wheat are deoxynivalenol (DON) and zearalenon (ZEA).

WC – Whole crop Crops are referred to as whole crops, when harvested before full ripeness as entire subsurface plant material mainly for silage preparation.

Definition of the Subject

Conversion processes in anaerobic digestion are realized by anaerobic prokaryotes that have been playing a major role in the transformation of chemical structures for a long period in evolution history. The product of such an anaerobic digestion process is a substance mixture. Its gaseous phase consists largely of methane and carbon dioxide and can be used for energetic purposes (Fig. 1).

The multitude of bacteria which are active within this anaerobic degradation process have the ability to digest a large spectrum of non-lignified biomass. Besides residual and waste biomass, the cropping of biomass (i.e., energy crops) is a possibility to supply larger amounts of biomass for anaerobic digestion processes.

Indisputable from a sustainability viewpoint is the fact that the land area for the production of agricultural goods is limited and that a conversion of land of high value for the storage of carbon or to sustain biodiversity should not take place. For this reason, the existing agricultural area should be used as efficient and

Biogas Production and Energy Crops. Figure 1 Schematic energy conversion process exemplarily demonstrated by the example of glucose without taking conversion losses into account

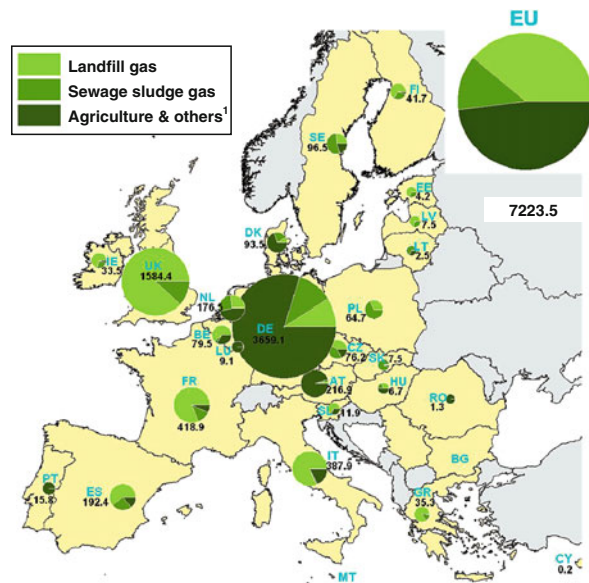

sustainable as possible also for energy provision. The cropping of energy plants can therefore be regarded as an important piece of a puzzle to complement existing production systems with its specific characteristics.

The agricultural production of substrates, which are the raw material for a sustainable substitution of fossil fuel energy, aims at designing systems that make a most efficient conversion of solar energy and a maximized substitution of fossil fuels possible. At the same time, all potentials should be utilized to ensure a long-term sustainability. Therefore, an intensive production and an environmentally sound production are to be harmonized. This article is going to concentrate on findings from Central Europe.

Introduction

Throughout the world, national legislations have introduced systems to promote an increased usage of biomass for energy production. Currently, in some countries incentive systems, which guaranteed fixed prices for electricity generated from renewable resources (feed-in-tariffs), are supporting this political goal [1, 2]. For example, by the amendment of the German Renewable Energy Act (Erneuerbare-Energien-Gesetz, EEG) in 2009, the German government put in place favorable conditions for biogas production. Tariffs set by this law guarantee degressive reimbursement for electricity from biogas for a period of 20 years. In addition to the basic reimbursement for each kWh dependent on capacity classes, additional premiums can be accessed. One of these premiums is a bonus payment for electricity from renewable raw material, which amounts to 0.07 €/kWh for plant sizes of up to 500 kW [3]. Similar incentives can also be found in other countries throughout Europe.

As shown in Fig. 2, the production of biogas from agricultural substrates contributes already noticeable to the overall Biogas production in Europe. The substrates currently used, for example, in Germany are dominated by animal excreta if the agricultural substrates are analyzed according to mass or volume. From an energy-related point of view, dedicated energy crops, which are again dominated by maize silage, make up the largest single share in Germany (Fig. 3).

Biogas Production and Energy Crops. Figure 2 Primary energy production from Biogas in Europe in 2007 in kilotons of oil equivalent [ktOE] (Data from [4]). ¹“Others” are the communal digestion of solid waste as well as the centralized CHP-usage of biogas fed into the grid

Biogas Production and Energy Crops. Figure 3 Substrate input in German biogas plants 2008/2009 – percentages of total fresh matter (left) (Adapted according to data from [5]) The shading is roughly indicating the energy yield of each substrate

The provision of energy crops is directly competing with food and fodder production. These two sectors are experiencing an advancing rate of specialization on a very narrow spectrum of crops in cultivation and

in a reduction in the number of crop types being rotated. The development of energy cropping as a new branch of production is therefore connected with the hope of providing possibilities for diversification in the context of a multifunctional agriculture [6]. High land productivity, maximum energy gain involving cost effectiveness and the optimization of non-commodities of cropping systems embedded in existing production regimes are major objectives of focus in public research.

Production and Provision of Energy Crops for Biogas Production

Biological and Agricultural Basis

The efficiency of the yield formation of agricultural crops is determined by an interaction of growth factors, that is, factors that are necessary for the metabolic processes of plants. These include solar radiation, temperature (progression), soil characteristics, and water availability as well as a controllable supply of macro- and micronutrients. For the choice of suitable crops and the design of cropping systems, the knowledge of these interactions is essential. The influence of the specificity of growth factors on yield can be roughly depicted by yield functions.

Efficiency of Photosynthesis The production of energy crops is, just as the entire plant production, based on the photosynthetic activity of higher plants. Ensuring a high efficiency of transforming solar radiation to simple organic carbon compounds, which are available for the formation of complex substances of content, is therefore a precondition for high energy yields.

The chain reaction involves the storage of solar radiation in energy-rich phosphate compounds. These are utilized to incorporate CO_2 into the acceptor molecule Ribulose-1,5-bisphosphate (RuBP) by means of the activity of the enzyme Ribulose-1,5-bisphosphate carboxylase oxygenase (RubisCO). As can be derived from the name, the enzyme also acts as an oxygenase. Hence, energy losses in the process of energy fixation are experienced. This part of the respiratory processes, which depends on the relation of O_2 -to- CO_2 partial pressure, is called photorespiration.

Some plant species, which due to their differing physiology are called C_4 plants, possess an intra-leaf

mechanism that enables them to retain CO_2 in their mesophyll cells. As this can result in CO_2 concentrations of up to 20 times as high as in most plants, C_4 plants have major advantages in efficiency. The fact that sufficient CO_2 is available for metabolic processes results in a minimized loss from photorespiration. Furthermore, with an increased photosynthetic activity, plants can respond to high light intensities, whereas insufficient concentrations of light are the limiting factor for most C_3 plants in solar radiation of more than 250 W/m^2 . This explains why only C_3 plants can profit from an increase in CO_2 concentrations in the atmosphere (Fig. 5).

The efficiency of photosynthetic processes is theoretically determined by the amount of primarily generated carbohydrates in relation to the radiation provided. According to the basic processes of photosynthesis, theoretical values of more than 30% for assimilation in the chloroplasts can be calculated. In fact, efficiency values are limited by some inevitable losses.

Only a part of the solar radiation in the spectral range of 400–720 nm can be absorbed by pigments in the membranes of the chloroplasts. In relation to the overall radiation, this bandwidth covers only about half of the total energy reaching the earth's surface. Losses from absorption by photosynthetically inactive structures and from transmission and remission amount to at least 9%. Roughly, 8.5% of the primordial radiation is lost during absorption by pigments as thermal energy. This can be explained by the fact that the energy of the different photons within the bandwidth exceeds the energy needed for driving the separation of charges. The transportation of electrons and the secondary processes of carbon assimilation require 19–22%. Processes of photorespiration and dark respiration use another 6.2–7.3% in C_3 -plants; dark respiration in C_4 -plants accounts for 4.9–5.8% of the losses relating to primordial energy. The differences in these ranges confirm the advantage of C_4 -plants in terms of efficiency. In a nutshell, different authors published an overall maximum efficiency level of 5.1% (C_3) and 6% (C_4) in chemically fixed energy in relation to the available radiation energy [7–14].

Efficiency levels that can be practically achieved are significantly lower. Maximum levels that could be measured in field experiments may reach a level of about 3.8% [15].

From the agronomists' point of view, it is vital that growing conditions are designed to allow for an approximation to the photosynthetically set limits of growth during the vegetation period. Harvesting and

the reestablishment of a sufficient leaf-area index in the successive crop limit the time span for an optimized utilization of the progression of solar radiation in temperate climates (Fig. 4).

Biogas Production and Energy Crops. Figure 4

Potential of plant production derived from the radiation levels available (1); percentage of available radiation used by the crop stand (2); and calculation of daily increment (3) for potatoes, sugar beet, and winter wheat ([16] according to [17])

Temperature and Water Usage All processes determining plant growth are influenced by temperature. Depending on the species, a temperature range supplying optimum conditions for growth can be defined. C_4 -plants show higher optimum levels (above 30°C) than C_3 -plants (around 20°C). This can be explained by the relatively lower affinity of RubisCO for CO_2 . Additionally, in warm conditions, CO_2 has a relatively lower solubility level in comparison to O_2 . However, if temperatures are too low, the higher energy exertion for the refixation and transport of CO_2 by C_4 -plants can be observed; this explains why the efficiency advantage of these plants can only be realized under conditions of adequate temperatures (Fig. 5).

Furthermore, temperature has an essential influence on the water balance of crop stands. This balance is decisively determined by the transpiration of leaf surfaces and the uptake of water by the roots. Due to the temperature-dependent differences in water potential between the atmosphere and the soil, water can move through the plant transporting nutrients and perform its essential functions in all the metabolic processes of the plant.

Of utmost importance is the evaporation through the stomata, by which gas is exchanged with the surrounding. The opening of the stomata is regulated,

which accounts for the fact that water and gas exchange processes of plants are directly related to each other. This also explains why the available amount of water during the vegetative span, as well as the efficiency of its usage is crucial for crop yield and security.

During the growth period, values for the evapotranspiration coefficient (ETC) of about $350 \text{ l H}_2\text{O/kg DM}$ for winter wheat, about $250 \text{ l H}_2\text{O/kg DM}$ for winter rape and approximately $200 \text{ l H}_2\text{O/kg DM}$ for maize could be identified. Due to different growth periods, ETCs of winter-annual crops are higher than those of summer-annual crops. By nature, low temperatures and low radiation intensities limit the growth of winter crops during long periods, so in relation to the available water, only little growth can take place. Hence, water consumption during the main growth periods should be regarded. In fully developed and healthy maize stands, this ranges roughly between 3.7 and 4.3 mm/day. Due to the described intra-leaf mechanism of CO_2 -refixation, maize, just like other C_4 -plants, exhibits higher water use efficiency (WUE). Still, necessary amounts of water cannot be provided by precipitation, which in the largest part of central Europe averages only between 1.6–2.5 mm/day. Therefore, with an increased optimization of other growth factors, also in temperate regions, water increasingly becomes the central limiting factor for plant yields.

In addition to the spatiotemporal distribution of precipitation, the soil functions of retention and storage of water from times in which water cannot be used for main growth periods is becoming increasingly important. Field capacity as well as the depth in which plants can potentially take up water by their roots is strongly determined by soil texture. In dry years, the effective root zone can vary between 50 (coarse sand) and 110 cm (loamy silt). By combining values of field capacities and effective root zone, the maximum amount of stored water available for plant growth varies between 30 and 220 l/m^3 . From this quantity of water in combination with the amount of precipitation water added and the water use efficiency of plants, limits for the potential yield of crop stands under the given conditions can be estimated.

Biogas Production and Energy Crops. Figure 5 Theoretical energy conversion efficiencies of photosynthesis of C_3 - and C_4 -plants as a function of temperature and CO_2 -concentrations of the surrounding environments [14]

Soil and Nutrient Supply Soil development is based on the processes of physical and chemical weathering and the successive translocation of surface rock substratum. Besides minerals of varying size and composition, air, water, and organic mass are part of the layer called the pedosphere. The organic mass contains dead biomass as well as living organisms that are involved in matter-transforming processes.

Plants depend on absorbing all mineral nutrients (oxygen and carbon excluded) and trace elements from the soil. Therefore, physical and chemical properties of soils are essential for the attainment of yield potentials. Besides the thickness of the top soil layers, soil texture plays an important role. By structuring adhesion forces in the differently large pores, soil texture significantly determines the water storage capacity of soils (see above) and the capillary rise of water from deeper levels.

Products from the weathering and transformation of matter also determine the ability of soils to store nutrients. The enormous surface area of minerals, which are part of the clay fraction, can fix ions that are dissolved in water (e.g., nutrient salts) in the process of adsorption. This protects them from being eluted; due to the reversibility of the process, they are still available for plants.

Other than the composition of mineral constituents of the soil, organic matter, which is supplied to soils and subsequently underlying constant de-, trans-, and reformation processes, is relevant for storage functions. Input matter for dead organic material, called humus, is mainly made up of harvest residues, green manure, and organic fertilizers such as fermentation residues from biogas plants. The enormous plurality of forms in which organic matter in soils exists can be structured by its stability with regard to decomposition processes. Non-humic substances like polysaccharides, amino acids, and P-compounds show little resistance to decomposition. In the course of decomposition, plant nutrients such as nitrogen (N), sulfur (S), and phosphorus (P) compounds as well as potassium (K), sodium (Na), magnesium (Mg), and calcium (Ca) salts are released.

Parts of the organic matter, intensively altered with regard to morphology, show stabilization against

further decomposition processes. These so-called humic substances form a large reservoir of nutrients due to their large exchange capacity. Furthermore, humic substances can occlude particulate organic matter within their structure and form compounds with clay minerals. This, in addition to its positive influence of transformation and storage functions, leads to a friable soil structure and the so-called mellowness of the soil [18].

For maintaining central soil functions and a constant flow of nutrients, a steady recirculation of organic substances is necessary. Since most forms of energy cropping aim at maximizing the energetic utilization of aboveground biomass, conflicts of interests can arise (see section [Humus Balance](#)).

From the perspective of plant production, planning the recirculation of residues is part of plant nutrition strategies. Central tasks in this planning are therefore to optimize the nutrition supply for the plants as well as to sustain and improve soil functions. The basic principle is that nutrients withdrawn from the soil should be returned. According to current knowledge, at least 14 elements are necessary for the normal development of plants. Quantities needed vary between the development stages, though.

The strongest influence on yield is to be seen in the variation of nitrogen supply. The reason can be found in the fact that nitrogen (N) is largely relevant to mass development and that its prevalence in most soils, relative to other nutrients, is yield-limiting. The uptake from soils mostly happens in the form of Nitrate (NO_3^-) or Ammonium (NH_4^+) ions. Besides organic fertilizers, the fixation of atmospheric elementary nitrogen in the course of cultivating legumes as well as the atmospheric deposition (caused, for example, by nitrogen emissions from combustion processes), the most important nitrogen source is mineral fertilizer. In contrast to nitrogen drawn from processes of the decomposition of organic matter, mineral fertilizer allows for a more pinpoint application.

Apart from nitrogen, fertilizer application of phosphorus (P) and calcium (Ca), as well as, depending on geological origin of the soil, of potassium (K) and Magnesium (Mg) has to be undertaken regularly. Phosphorus (P) is taken up by plants mainly in an

inorganic form (H_2PO_4^- und HPO_4^{2-}). It has a key function in energy-related processes and is a component of organic compounds that are crucial for a plant's life. Potassium, Magnesium, and calcium are taken up as cations (K^+ , Mg^{++} , and Ca^{++}) from the soil. Potassium is used for osmoregulation and influences numerous enzymatic reactions, which are important for the formation of macromolecules. Transportation of assimilates, winter hardiness, and drought resistance are raised by a good supply with potassium. Likewise, Magnesium is a nutrient for constructional and functional purposes. It is used in oxidation processes of the chlorophyll during radiation impact and is employed in energy-related metabolism as well as for the activation of enzymes. Calcium is an important component of the plants' matrix structure but also accounts for the bulking state of plants and the activation of various enzymes. The application of calcium is mostly aimed at regulating pH-levels for the optimization of nutrient availability for plant nutrition. Furthermore it stabilizes soil texture due to its bond-building function, which prevents puddling, erosion, and oxygen shortage. Other nutrients

are available in sufficient quantities in most central European agricultural soils.

The amount of nitrogen fertilizer given should be oriented at the withdrawal of the plant stand. One of the central challenges is to plan optimum quantities before knowing the realizable yield. From an economic point of view, the optimum amount is characterized by the fact that the cost of the last unit of nitrogen given should be covered by the net revenue of the additionally attained amount of yield (marginal revenue). By approaching and exceeding the maximum attainable yield, the latter decreases (Fig. 6).

An optimized application of fertilizer, which avoids sumptuary consumption, can contribute to minimizing negative effects on the environment. Such negative effects are, for example, the leaching of nutrients into deeper soil layers, groundwater or receiving streams, nitrous gas emissions or the loss of nutrients into ecosystems by means of erosion processes. Risks of nitrate leaching are particularly high. Therefore, within Europe various regulations exist regarding fertilizer application.

Biogas Production and Energy Crops. Figure 6

Relation between nutrient supply in the soil and in the plant respectively and the yield [19]

Organic Substance Groups as Raw Material for Anaerobic Digestion

The different substances incorporated in plant matter show, depending on their specific composition, a differentiated suitability for decomposition in anaerobic processes. Therefore, they can contribute in a differentiated manner to biogas and methane formation respectively which means, that the composition of plant matter plays a decisive role for the usability of chemical energy fixed in the substrate.

Organic Substance Groups The primary substances formed in the process of photosynthesis and the higher-molecular carbohydrates, lipids, and proteins formed in the following metabolic processes serve for the formation of the matter of plant cells, which are largely composed of macromolecules. The structure of these macromolecules follows universal laws; largely, they are formed according to the principle of replication from smaller units that are similar or congeneric.

For an assessment of the transformation of differently composed material, long-term experiences in the field of ruminant nutrition can be referred to. The analysis of plant material and its description can be conducted by the *Weende Analysis Standard* and its extension by van Soest [20]. This standard does not produce exactly defined chemical substances as parts of the cell wall or cell interior, but it can deliver statements on the energy value and the usability for digestion processes.

Internal Cell Substances In the field of ruminant nutrition, those parts of the cell substance that are soluble in a neutral detergent are called internal cell substances. A further subdivision can be done by classifying the different substances as part of different nonstructural carbohydrates, crude protein, crude fat, crude ash, or as part of the residual fraction.

Crude ash is the inorganic part of the assay, which remains after incineration. Still, the minerals remaining are mostly not isolated constituents of plant matter but are mostly part of organic compounds. Crude protein includes the actual protein fractions as well as the nonprotein nitrogen compounds. Being the nitrogen-consisting fraction, crude protein is being calculated from the nitrogen

content of the assay and the average nitrogen content of proteins.

All substances that can be extracted using ether are called crude fat. Apart from actual fats (Triglycerides), this fraction also includes fat-like substances (lipoids). Nonstructural carbohydrates can be subdivided into water-soluble carbohydrates; that is, sugars and fructanes that consist of a buildup of laevulose components as well as starch, which functions as the most important reserve carbohydrate build up of sugar components. All other substances soluble in a neutral detergent are called organic residues and mostly consist of organic acids.

Cell Wall Substances (Skeletal Substance) Those parts of plant matter that are not soluble in a neutral detergent are called cell wall substances or NDF (neutral detergent fiber). A further subdivision can be made by classifying the different substances as part of the fraction of structural carbohydrates (pectins, hemicelluloses, and cellulose) or lignin.

Cellulose forms the skeletal substance of the non-lignified cell walls and is relevant for the tensile strength of the plant. The buildup is formed by the connection of monosaccharides (D-Glucose) by hydrogen bonds. The collective term hemicellulose includes a variety of other polysaccharides. Unlike cellulose, these consist of a variety of different monomers and a branching buildup. In combination with pectins and most of all, lignin, hemicellulose forms the cell wall matrix in which cellulose fibers are embedded. In the course of plant development and aging, the share of the different components in the cell wall changes. From primary to secondary cell wall structures, the share of pectin and hemicellulose falls while the share of lignin rises.

Analytically the combination of cellulose and lignin can be found as insoluble substances in acid detergent (ADF: Acid detergent fiber). Approximately, this fraction is comparable to the former crude fiber content of the *Weende Analysis Standard*, which comprises a lesser detailed subdivision of substance groups.

Figure 7 shows the development of different substance groups during the generative phase from the example of a maize plant. The change of cob mass in relation to the mass of the rest of the plant due to an increased storage of starch becomes very obvious.

Biogas Production and Energy Crops. Figure 7

Development of the dry matter content (DM%) and substance composition of a maize plant from flowering to threshing ripeness (subdivided into cob and stover) ([21], complemented and altered)

Biogas Production and Energy Crops. Table 1 Substance composition of different energy plants for potential use in anaerobic digestion (Data from EVA – project [22, 23])

Crops	Crude Ash	ADL	Cellulose	Hemicellulose	Organic Rest	Crude Protein	Crude Fat	Starch	Sugar
Maize (early dough/dough)	4.3	3.4	23.1	22.8	9.5	8.0	2.5	15.6	10.8
Sugar beet, clean	16.6	0.2	21.0	21.6	0.6	15.9	2.1	0.0	22.0
Winter triticale WC (medium milk – early dough)	4.8	4.8	27.8	22.7	8.0	8.4	1.8	7.4	14.4
Clover grass first cut	9.8	2.8	28.2	11.8	17.4	13.7	3.0	1.6	11.7
Clover grass third cut	12.1	5.6	27.5	8.0	18.0	16.6	3.3	3.7	5.2
Cup plant	9.7				8.3	19.8	1.8		
Sorghum (<i>Bicolor</i> × <i>sudanense</i>) (up to early dough)	5.4	5.9	30.9	25.5	7.4	8.5	1.7	3.5	11.1

WC whole crop

At the same time, due to the transport and transformation of sugars as well as the lignification of the cell wall (characterized as crude fiber) and the digestibility of the stover sinks considerably.

Accordingly, Table 1 shows characterization of potential energy plant substrates for silage preparation. Values are given for “optimum” harvest dates for ensiling processes and anaerobic digestion.

Substrate Requirements and Biogas Yields Simple carbohydrates, fats, and proteins are the most accessible nutrients for bacteria involved in the process of anaerobic digestion. Thus, substrates containing high percentages of sugar and starch can be used to react quickly to low supply situations of the bacteria. Lignin, on the other hand, can be characterized as inert inside the fermenter and has no value for biogas production. Cellulose and hemicellulose form an interim position (Fig. 8). Also the digestibility of these groups can be limited by their being included in lignin–cellulose–hemicellulose complexes. In addition to the share of lignin, a mass of approximately 1.4 times this amount cannot be digested by the bacteria involved [24].

Planning of fermenter volume and the retention time or volume load is therefore also linked to the characteristics of substrates. The larger the share of slowly digestible substance groups, the larger the size of the fermenter to be constructed, in order to allow for an extensive digestion of organic matter (e.g., [25]).

Additionally, in planning other parts of the biogas plant, the feedstock plays a major role. Feeding, stirring, and pumping/discharging technology should be chosen according to the characteristics of substrates, for example, regarding the tendency to form deposition or floating layers [27].

While these characteristics influence the investment cost, the direct revenue of feedstocks is largely depending on their specific biogas formation potential.

An approach to the derivation of the biogas formation potential is to be seen in stoichiometric calculations (e.g., [28–31]). According to these sources, the elementary composition of plant material (C, H, and O) allows for an approximate estimation of the gas formation potential (see, e.g., Table 2).

Due to the fact that values are calculated for a complete digestion of substances for the derivation of practically achievable yields, it is necessary to involve the actually digestible share of each substance group. One frequently used approach is to be seen in the utilization of digestibility coefficients known from feeding experiments, which are multiplied with potential methane yields (e.g., [32] based on [22, 30]). Despite various formulas that have been suggested (e.g., [33–35]), the usability for a wide range of plant and substrate types is limited in its validity, due to a so far non-sufficient parameterization for different plants and harvest stages.

Another possibility is the identification of gas yields using laboratory methods, for example, the utilization of batch tests (e.g., [36]). Methane yields for different energy crop substrates are shown in Fig. 9. Based on findings from different plant species a correlation between methane yield and the lignin content ($R^2 = 0.78$) or the sum of lignin and cellulose ($R^2 = 0.60$) can be seen [37]. Low methane yields of the Asteraceae sunflower and Jerusalem artichoke as well as *Miscanthus* go along with high lignin shares in plant matter.

Biogas Production and Energy Crops. Figure 8
Digestion time of different substances [26]

Biogas Production and Energy Crops. Table 2 Potential and composition of biogas from different substance groups [31]

Substance group	Molar weight (g/mol)	Molar share of CO ₂ and CH ₄ in biogas (mol)	Molar volume of biogas (g/mol)	Potential biogas yield (l/g)
Carbohydrates C ₆ H ₁₂ O ₆ or (CH ₂ O) _n	180	3 CO ₂ + 3 CH ₄	6·22.4 = 134.4	134.4/180 = 0.746
Fats, e.g., Palmitin C ₁₆ H ₃₂ O ₂	256	4.5 CO ₂ + 11.5 CH ₄	16·22.4 = 358.4	358.4/256 = 1.39
Proteins incorp. 21 amino acids C ₁₃ H ₂₅ O ₇ (N ₃ S)	367	5.125 CO ₂ + 7.857 CH ₄	13·22.4 = 291	291/367 = 0.79
Plant biomass C ₃₈ H ₆₀ O ₂₆	932	18 CO ₂ + 20 CH ₄	38·22.4 = 851	851/932 = 0.91

Biogas Production and Energy Crops. Figure 9

Methane yields and lignin content of silages from different plant material. Values shown are identified according to VDI 4360 and do not include ensiling losses. ([37]; sugar beet according to [38]; cup plant calculated value according to [39])

Since minerals (ash) do not hold a proper methane formation potential, gas yields are given as the potential per unit of organic dry matter (unit: liters under standard conditions for temperature and pressure per kg of organic dry matter l_N/kg DM).

For the metabolic processes of bacteria, which are involved in the process of digestion, a variety of minerals are required. Roughly a relation of 600:15:5:1 of C:N:P:K is regarded as optimal [27]. A lack of availability of elements such as nitrogen

(C:N > 40) can limit the growth of bacteria. The same applies for potassium, sodium, calcium, and a variety of other trace elements (e.g., Co, Ni, Mo, Se, Fe). Optimum concentrations are commonly approximated at between 1 and 10 mg/l for iron, 0.005–0.5 mg/l for Nickel, 0.003–0.06 mg/l for cobalt, and 0.005–0.05 mg/l for Molybdenum. For co-digesting manure, a sufficient supply of bacteria is, in most cases, provided. With very high concentrations of nutrients, risks of inhibition of digestion processes rise.

Accordingly, nitrogen can lead to toxic reactions and the inhibition of bacterial activity by the formation of ammonia (C:N < 15:1). High sulfur values can lead to the formation of hydrogen sulfide, which – in sparsely adapted conditions in the fermenter – can lead to inhibitions at concentrations of 50 mg/l and above. Furthermore, its corrosive impact on copper and copper-compounds should be mentioned. Table 3 shows data on critical concentrations. It should be noted though, that vast interactions between

inhibitors limit the force of expression of single values. Additionally, bacteria involved are able to adapt to and, in some parts, even decompose some inhibiting compounds [40].

Apart from the crop used, substrate characteristics can also be influenced by the date of harvesting, the choice of which should aim at optimum yield and conservation properties (Fig. 7). Choice of crops can influence soil input into the fermenter, which can lead to deposition layers such as in the case of sugar beet (below). Furthermore, chopping size, which influences the surface area prone to microbiological attack as well as the tendency of a substrate to form floating layers, are factors influencing the fermentation process.

Production Systems for Different Energy Crops

Intensive breeding work and optimized production systems were able to contribute to a major increase in the yield of agricultural crops during the last decades. Therefore, many of the crops used for biogas purposes are crops known from food or feed production, which are harvested at the time of maximum biomass yields for silage preparation.

Besides crops from the family of *Poaceae* (true grasses such as maize, sorghum, and other cereals), leaf fruits like sugar beet can also be used. Currently, perennial types of the family of *Asteraceae* (aster family), *Malvaceae* (mallow family), and *Polygonaceae* (knotweed family) are also in discussion. *Brassica* (mustard family) types are not suitable due to high sulfur contents in the plant material.

Maize

Distribution and relevance Worldwide, maize (*Zea mays*) is one of the major agricultural crops. It belongs to the family of true grasses (*Poaceae*) and is a C₄-plant. Globally, it is dominantly cultivated for food production as grain maize. The cropping of maize in temperate climates could be extended largely by the development of adapted breeds that were developed during the last decades. In temperate climates, silage maize (SM) for fodder production (harvesting and ensiling at dough stage, Fig. 7) is of highest relevance. Regionally, the cropping area of maize has been increased by an increased biogas

Biogas Production and Energy Crops. Table 3 Critical concentrations of different inhibitors in biogas reactors. Shown in brackets are values for adapted bacteria populations [40]

Inhibitor	Critical concentration
Sodium	6–30 g/l (60 g/l)
Potassium	3 g/l
Calcium	2.8 g/l CaCl ₂
Magnesium	2.4 g/l MgCl ₂
Ammonium/ ammonia	2.7–10 g/l (30 g/l)/ 0.15 g/l
Sulfur	50 mg/l H ₂ S; 100 mg/l S ₂ -160 mg/l Na ₂ S (1,000 mg/l H ₂ S; 600 mg/l Na ₂ S)
Nickel	10 mg/l
Copper	40 mg/l; carbonate 170 mg/l
Chrome	130 mg/l; carbonate 530 mg/l
Plumbum	340 mg/l
Zinc	400 mg/l; carbonate 160 mg/l
Iron	Carbonate 1,750 mg/l

production (Fig. 2). To some extent, new breeds sold especially for biogas production are grown (see section “Breeding”).

Demands on site and climate Maize requires 200 mm of precipitation during its vegetation span, whereas the main demand is set during the flowering period. The crop is less demanding with regard to soil type; however, more importance is given to soil structure. A good supply of nutrients and water is only guaranteed if the soil is well penetrable for rooting. For germination, a soil temperature of between 8°C and 10°C is needed.

Temperature remains largely the limiting factor in temperate climates. Even precocious breeds demand minimum mean air temperatures of more than 13°C during summer months (May to September) [41]. Temperature sums can therefore provide information for choosing a breed adapted to the site-specific growing period. They are also used for harvest date prognosis models.

An international classification of maize breeds, albeit not specified by utilization purposes, is given by the three-digit FAO number. The first and second digits refer to ripeness classification and subclassification respectively. Under central European conditions, a difference of 10 units roughly describes a difference in ripening of 1–2 days [42]. Breeding approaches aiming at the provision of breeds for the specialized purpose of biogas production use breeding material with higher FAO classifications. Yield increases could be noted on comparatively warm sites. The difference in FAO numbers should not exceed 30–40 due to the danger of not reaching sufficient dry matter values of >30%.

Distinctive aspects of cropping system Commonly, sowing is done with single-seed sowing techniques with row distances of 75 cm. A low coverage level during early summer (around June) leads to a comparably high exposure to the increasingly erosive precipitation. Accordingly, on sites with a slope of more than 5%, erosion risks have to be taken into account. These risks can be encountered by using lower row width, under-sown crops, or non-tillage systems. Non-tillage systems can be well used after the harvest of a winter (first or inter-)crop for the establishment of maize. To avoid yield risks, slow

development in early growth stages also makes weed control necessary.

Some investigations point out an influence of the harvest date on the specific methane yield of maize, while other results show no significant changes within the possible harvest time [43, 44]. Despite the possibility of higher methane yields (l_N/kg oDM) at early stages, investigations have shown that dry matter increment during the ripeness phase makes higher overall methane yields per hectare possible [35, 43], so most probably, substrate quality issues for ensiling (maximum 35% DM) determine optimum harvest date.

Apart from the high efficiency in using available water resources, the nutrient efficiency of maize is also very high. Per ton of dry matter, a withdrawal of 11–13 kg N, 2.1–2.6 kg P, 12–13.5 kg K, 2.5–3 kg Ca, and 1.8 kg Mg is a common range for analysis and for the estimation of the required amount of fertilizer.

Sorghum

Distribution and relevance Sorghum, just like maize, is part of the true grasses (*poaceae*) family and a C₄-plant. Cropping of sorghum is most relevant on the African continent, where it is mostly grown for grain utilization for food purposes. In the USA, sorghum is also highly relevant for silage preparation especially in the regions of the Great Plains where other fodder crops risk high yield losses due to summer drought. *Sorghum bicolor* and *Sorghum sudanense* as well as hybrid breeds of *Sorghum bicolor* and *Sorghum sudanense* are currently discussed and tested as substrates for biogas production.

Demands on site and climate The different sorghum types have a much higher demand regarding temperature conditions in comparison to maize. For germination, minimum soil temperatures of 14°C are needed [45]. Temperature sum from May to October should at least add up to 2,000°C (>5°C) [46]. Sorghum is frost-susceptible: Below temperatures of 4°C, it can suffer cold injuries.

To develop its characteristic rooting, sorghum breeds require deep soils without compactions. Despite slower root development, the subsequent deep rooting makes it possible to adequately utilize soil water and hence leads to good drought resistance properties and very fast growth during summer months. Compared to

maize, this is one of the decisive advantages of sorghum breeds (e.g., [47, 48]).

Experiments in Central Europe show a high yield potential for sorghum breeds. In many cases, the duration of the vegetation span was not sufficient for the development of sufficient dry matter values [49].

Distinctive aspects of the cropping system Sowing can be done with standard drill sowing techniques at a depth of about 2–3 cm. After a rather slow development in early development stages (especially in low temperature conditions), sorghum breeds show a rapid growth. In contrast to maize, sorghum tillers with 2–3 (bicolor – breeds) or 4–6 (*sudanense*/*sudanense* × *bicolor* – breeds) shoots respectively. *Sudanense* and *sudanense* × *bicolor* types can potentially be harvested more than once a year. Advantages in yield are not to be expected under Central European conditions and dry matter contents will not be reached in any of the cuts.

The height of sorghum breeds can exceed 4 m; however, it should be mentioned that tall-growing breeds often lack a sufficient stability. Sorghum shows a good appropriation of nutrients and can accordingly, similar to maize, make use of organic fertilizers. Withdrawal of nutrients for silage sorghum equals approximately 11 kg N, 4 kg P, 12.5 kg K, 1.5 kg Ca, and 1.2 kg of Mg per ton of dry matter.

The high sugar content of more than 20% for many *bicolor*-breeds (which are also specified as *Sorghum bicolor* ssp. *Saccharatum*) [50] lead to comparatively good ensiling properties. On the other hand, the lignin/crude fiber content is comparatively high, which leads to methane yields per mass unit that are around 10% lower than those of maize. In some breeds, there are high values in hydrocyanic acid, which are problematic for utilization as fodder but however do not inhibit anaerobic digestion properties [51].

Whole-Crop Cereals

Distribution and relevance Whole-crop cereals are cereals yielded from the early milk stage for silage preparation by the utilization of the entire plant matter. Generally, all cereals that are productive in market cereal production are suitable for this utilization purpose. In Central Europe, this encompasses predominantly wheat, rye, triticale, and barley. Due to their higher yield

expectancy, winter forms are preferred for substrate production. Grain-straw ratios in earlier literature suggested a high yield potential of the summer-annual oat; though, this could not be confirmed in testing newer breeds [49].

Demands on site and climate Winter forms of cereals are sown in autumn and demand the impact of cold temperatures during early growth (vernalization) to be able to proceed to the generative phase. This period of cold temperatures is shorter in winter barley (20–40 days) than in winter rye and winter triticale (30–60 days) and winter wheat (40–70 days). Spring forms of cereals do not demand vernalization and are sown as early as possible in spring (Central Europe: March). The gradation in genotype disposition, in terms of temperature demand and photoperiodic reaction, therefore play a major role for the question of suitability.

Germination of cereals starts at low temperatures. Rye has the lowest demand with temperatures of 1–3°C. Minimum temperatures for the net primary production of most cereals are around 3–5°C, and for oats between 4 and 6°C. Winter hardiness differs between the different types of cereals. While winter rye can sustain snowless frost periods with temperatures of up to –25°C, temperature values of around –20°C for winter triticale and winter wheat and of around –15°C for winter barley can be sustained. After field emergence in spring, oat can also sustain frosts of –6°C.

Winter wheat has the highest water and soil requirements and – when provided – shows high productivity. On lighter soils, rye can produce yields similar to those of winter wheat. Barley also has fairly low requirements concerning soil quality. Triticale, as a cross of wheat and rye, was supposed to combine the relatively low requirements of rye with the high yield potentials of wheat. High whole-crop yield potentials on sites providing good soil characteristics can be confirmed. Since the crop ratio of comparatively high-yielding wheat is already high on accordant sites, winter triticale is being recommended because in addition to its high-yielding potential, its cultivation provides possibilities to extend crop rotations (see section “[Cropping Systems](#)”). On low-yielding sites, winter rye has the best suitability in whole-crop cereal production as

well. Rye shows higher self-compatibility than wheat, which lowers the necessity for alternatives.

Winter cereals, just as other C_3 -plants, commonly have lower water use efficiency than C_4 -plants such as maize or sorghum. The decisive advantage of winter annuality is that in temperate climates, during tillering and stem elongation stages, these plants can convert winter precipitation stored in soils much better into biomass.

Distinctive aspects of cropping system In general, cropping systems for cereals aimed at substrate production are to be oriented at market cereal production. From an agronomic point of view, during the last years, various options to reduce factor intensity have been discussed. These discussions were based on the changed quality requirements and the shorter growing periods of whole-crop cereals (see section “Factor Intensity”).

Biomass yield of cereals can increase until the stage of yellow ripeness. From then respiration of assimilates and loss of leaves lead to a net yield reduction [52]. For the choice of harvest time, considerations on intended silage quality and the establishment of a subsequent crop play a major role. For instance, during yellow ripeness, dry matter contents exceed the optimum range in many cases. Accordingly, simultaneous optimization of yield and ensiling properties, brings about short time frames for harvesting in most years at the end of milky stage. Since the correlation between dry matter content and the development stage is low, tentative testing of plant material before harvest is advisable. From the viewpoint of crop rotation design, harvest time can also be influenced by the choice of cereal. Winter barley reaches an optimum harvest time much earlier than winter wheat (Fig. 10).

Depending on the type of cereal and the harvest stage, withdrawal of nutrients from the early milk stage amount to 11–15 kg N, 2–2.5 kg P, 14–17.5 kg K, 0.9–1.2 t Mg, 2–3.2 kg Ca per ton of dry matter.

Cropping systems for whole-crop cereals should not be mistaken for intercropping systems. Green-cutting of rye, for which special breeds are sold, starts from the visibility of the first awns. Yield quantity can be approximated at around half of the yield of whole-crop yields. Due to low dry matter contents, swathing and pre-wilting is required in many cases.

Biogas Production and Energy Crops. Figure 10
Development of dry matter for winter rape, barley, rye, wheat, triticale, and oat on central German sites [52]

Yields of winter cereals vary, depending on site characteristics, according to grain production largely. On loess-influenced sites, yields of up to 20 t DM can be achieved. On sandy soils, yield expectations are approximately half of this value. Despite these major differences between the different sites, intertemporal yield variations on the specific sites are lower than those of maize.

Sugar Beet

Distribution and relevance Sugar beet (*Beta vulgaris* ssp. *maritima*) is mainly grown in Central Europe. As the beet may take advantage of large parts of the available vegetation period of temperate climates, it is one of the most yielding crops in those regions. Due to the reform of the Common Market Organization for sugar in 2006, sugar beet cropping for sugar production has sensibly gone down. As expertise and machinery still exist, there is growing interest for the utilization of sugar beet for other purposes. Therefore, technical equipment and machinery must be adapted correspondingly.

Other than sugar beet, fodder beet is of less importance. As they have low dry matter contents and the existing varieties lack resistance against Rhizomania,

leaf spot, or nematodes, it is at present not of interest to grow fodder beet for biogas production.

Demands on site and climate Sugar beet cropping is done best on deep, medium-heavy soils that allow good rooting. Therefore, chernozem and brown earth with loess with a stable soil structure and a high, usable field capacity are particularly well suited. From the point of view of substrate production, keeping troublesome substances away from the digester is an issue of decisive importance. Beets from sandy soils have less soil tare, while loam, clay, or silt adheres more easily to the beets. However, practical experience has shown that such particles stay in suspension due to agitating and pumping in the digester; they stick to organic matter and thus leave the digester with the residues. Sand, however, tends to sediment and form a layer. Another problem, which is much more dangerous, arises from stones, as they might damage the feeding system and the agitators. Therefore, cost-saving technologies to remove hazardous material before it gets into the digesters will be of decisive importance in the future. At present, mobile units to clean the beet are being developed.

Distinctive aspects of cropping system The sugar beet is drilled in rows with a special precision drill as soon as the soil is well settled and dry, and night frosts are not any more to be expected. It is better to drill later instead of disturbing and hindering the sugar beets' growth by soil compaction as a consequence of the wrong soil management.

In conventional sugar beet cropping, the extraction rate per ton of dry matter is around 8 kg N, 1.8 kg P, 9 kg K, 2.2 kg Mg (the root) and/or 22 kg N, 2.8 kg P, 27 kg K, and 3.3 kg Mg (leaves). The quality parameters of sugar production do not apply to sugar beet cropping for biogas production; fertilization programs may thus be modified. More nitrogen fertilization leads to disproportionate increase of leaf growth compared to root growth. Nitrogen fertilization should not be increased by more than 20% with regard to the level applied for sugar beet for sugar production. It may be that boron could be necessary at canopy closure to prevent from heart and root rot, especially if the beets are supposed to be stored in field clamps for a longer period.

Other than for sugar production, the grown biomass of beets should be used completely. When defoliating the beets, they are not topped but only stripped of their leaves, and the crown is harvested together with the root. This allows a surplus yield of 5–10% [53]. However, when using this method, sugar beets should be fed into the digesters before too long, as the leaves may start to regrow. Sugar beet leaves are to be considered an additional yield factor, as the leaves mean an additional fresh matter yield of around 3.5–4.0 t of dry matter/ha, the equivalent of up to 15% more methane yield per hectare. But as leaves contain less energy than the roots, in general only short transport distances are profitable.

As sugar beets have a low dry matter content and are therefore less suitable for silage, bridging the time between the moment the beet is mature and the moment it is fed into the digester constitutes a certain challenge.

Storing the fresh beets in clamps and feeding them into the biogas production plant is possible between the months of September through mid-February under Central European conditions. However, clamps should be covered by mid-November. When clamps thaw after long periods of frost, the beets should be processed as soon as possible. At present, it is checked whether the beets may remain in the soil during winter and be harvested before bolting. Compared to storage in clamps, relatively mild winters thus allowed gaining yield surpluses of 10% [54]. With less favorable conditions and strong ground frosts, however, it is necessary to harvest and process the beets as quickly as possible.

When beets are to be stored for a longer term, they must be ensiled. The latest findings open up the following possibilities:

1. Ensiling in plastic tunnels: Up to now, good experiences have been made with ensiling whole beets. Chopped beets in foil tunnels would run the risk of causing the tunnel to burst due to the resulting seepage.
2. Ensiling entire beets in bunker silos: The density of the sugar beets changes in the course of the ensiling process. The piles slump down to almost half the height during ensiling. Sampling of such beets has shown pH-values of 3.5. In any case, it is important to collect the seepage.

3. Ensiling as mixed silage with maize: Good experiences have been made during the past years with mixed silage (maize/sugar beets in layers with a ratio of up to 50/50) in bunker silos. The main challenge consists of finding an optimal harvest date for sugar beets and maize, and coordinating two harvesting processes for different crops at a time. For example, in large parts of Germany, maize is harvested during mid-September until the end of the month – a time, where sugar beets have not yet reached their maximum yield. Therefore, a late maize variety should be chosen (see section “Breeding”). Another possibility is ensiling beets together with dryer substances, for example, ground ear maize (GEM). In such cases, even a ratio of up to 70% of sugar beets would be possible.
4. Ensiling in existing tower silos: If tower silos already exist, they are useful. Main stress should be put on producing beet pulp which is as homogeneous as possible, to avoid sedimentation in the silo.

Depending on the storage method, it is necessary to provide for adequate chopping technique before and/or after storage. Practical experience has shown that when whole beets are stored, it is sufficient for fermentation needs to chop the beets to a size of 3–4 to 1 cm, to take advantage of the specific properties offered by sugar beets for biogas production.

These favorable properties are quick fermentation (Fig. 8), high methane yields (Fig. 9), easy pumpability, and a process-stabilizing influence compared to the specific acid values prevailing in biogas plants despite quick acidification in the digester when sugar beets are fed in [55].

Perennial Forage Grasses and Forage Mixtures

Distribution and relevance Multi-cut forage crops consist of annual and perennial grasses, small-seed legumes or mixtures including various types. In Europe, these were traditionally grown to provide protein-rich fodder for dairy cows. Due to the expansion of maize cropping, the crop ratio of perennial fodder plants decreased largely [42]. In Europe, grasses cultivated include mostly species from the *Poaceae* subfamily of *Pooideae*, mainly ryegrass (*Lolium*), Festuca (*Festuca*) and hybrid crossings (*Festulolium*) accordingly as well

as Timothy grass (*Phleum*) breeds and cocksfoot (*Dactylis glomerata*).

During the last years, perennial warm-season grasses of the *Poaceae* subfamily of *Panicoideae* such as Miscanthus (*Miscanthus Giganteus*), Andropogon (*Andropogon gerardii*), or Switchgrass (*Panicum virgatum*) were also tested for energy cropping in temperate climates. According to current knowledge, good yields can be achieved with warm-season grasses. For the utilization as a biogas substrate an extensive lignification (Miscanthus, Fig. 9), a lack of persistence or a high damage from early cuts proved to be disadvantageous [56]. As such, other conversion routes are more reasonable (see other article, e.g., on combustion).

Demands on site and climate Production of grasses and forage mixtures can be set on all arable sites. Mostly, it is advantageous on sites that are too cold for the cropping of maize or sorghum or where late frosts in spring or early frosts in autumn are to be expected. For the cropping of red clover (and grass mixtures), continental sites with average precipitation levels of 650 mm are most suited. Ryegrasses show suitability on fresh to moist sites with precipitation of more than 650 mm. Alfalfa (and grass mixtures) are advantageous on anhydromorph calcareous soils and weathered loess soils. Alfalfa and cocksfoot are also advantageous on drier sites.

Distinctive aspects of cropping system For an optimum choice, apart from site characteristics, the planned utilization period is of major importance. Generally, the cropping of mixtures is preferable due to weather and utilization conditions, risk minimization, and their higher adaptation potential to the specific site. Furthermore, the nitrogen fixation of mixtures, including legumes, as well as the positive impact of perennial grasses and mixtures on the humus balance should be included into the evaluation.

The choice of cutting frequency influences the specific methane yield as well as the yield of perennial forage cropping. In later and hence reduced cutting during the vegetation span, substrates may on the one hand become less digestible. On the other hand, yield increases. According to current knowledge, reduced cutting frequency, which means 3–4 cuts instead of 4–5 cuts can be advantageous and lead to a 10% increase in overall methane yields per hectare [57–59].

Due to the low dry matter content of the cuts of grasses and forage mixtures, fresh material shows low suitability for ensiling. Commonly, swathings and pre-wilting to a dry matter content of 30% is done before the work step of picking up under the precondition of sufficiently warm conditions.

Overall, during the main utilization years, yields of ryegrass mixtures on maritime influenced sites can exceed 20 t DM/ha, on better but in summer dryer continental sites, yield of 16 t DM/ha can be achieved. Multi-cut systems including production steps for swathings demand higher production costs per hectare. Due to low income of fodder production from permanent grassland, the utilization of these sites for energetic purposes might increase as well [60, 61].

Additional “New” Energy Crops Given the specific substrate requirements of the utilization pathway of anaerobic digestion, during the last years, the cropping of a range of other energy crops that have no or only little share in current cropping systems of temperate agricultural regions has been discussed. Whereas knowledge on the cropping of some of these plants as the cup plant (*Silphium perfoliatum*) or the Jerusalem artichoke (*Helianthus tuberosus* L.) exists, for other options, very little experience is reported.

Cup Plant (*Silphium perfoliatum*) The cup plant is a perennial plant of the aster family (*asteracea*) that originates from the temperate regions of North America. While little experience in agricultural cultivation has been made there, the plant was tested in the 1970s and 1980s in Japan, Russia, and Eastern Germany among others concerning its properties as a fodder plant [62]. Due to lack of seed production, cultivation could not be implemented practically.

Demands of the cup plant with regard to soil texture is not high; it can also be cultivated on sandy soils at fairly low annual precipitation levels of 350–440 mm. Water-logged soils are not suitable; best growth can be expected on humus sites with good water supply. For germination, seeds require a longer phase of cool or changing temperatures.

For the establishment of practically applicable cropping systems, current works focus on the pretreatment of seed and single-seed sowing techniques – currently establishment has to be done,

using seedlings. During the year of establishment, plant development is slow and no linear growth takes place. Weed control is necessary. Planting should be finished at the beginning of June, to tap the full yield potential from the second year on. As a utilization period, a 15-year period is currently being focused on. Nutrient withdrawal amounts to 10 kg N, 1.9 kg P, 16–17 kg K, and 4 kg Mg per t DM.

Harvesting starts from the flowering period at dry matter contents of 28–30%. Ensiling properties are good and deliver methane yields that are slightly lower than those of maize at 300 l_N/kg DM (Fig. 9). Yields of 17–20 t DM/ha from the second year on better soils [39] and 12 t DM/ha on weaker soils [63] can lead to the appraisal that the cup plant might in future be a new crop for energy production in temperate climates.

Jerusalem Artichoke (*Helianthus tuberosus* L.) Jerusalem artichoke is, like the cup plant, part of the aster family (*Asteraceae*). Instead of starch, the plant uses Inulin, a fructose-polysaccharide, as a reserve carbohydrate. This is stored in irregularly shaped tubers measuring up to 10 cm in diameter from which several pith-filled stems of up to 3 m in length are formed.

Jerusalem artichoke also grows on sandy soils and shallow alteration soils. High yields require a good water supply during summer months. For the utilization of the tubers, the same restrictions apply as for the utilization of sugar beet. This means, that sites should be avoided, that entail an intensive input of soil, especially sand and stones into the fermenter.

Since plants do not reach seed ripeness in temperate climates, reproduction is done vegetatively using potato planters for the deposition of tuber. Choice of breeds and planting density depend on the utilization aim. For the utilization of aboveground biomass, the planting density is lower (about 40,000 tubers/ha) than for the utilization of tuber biomass itself (45,000–50,000 tubers/ha). Nutrient withdrawal ranges at approximately 10–12 kg N, 2–3 kg P, 23–25 kg K, and 2 kg Mg per t DM of tuber and 7.5 kg N, 0.8 kg P, 20–21 kg per ton DM of the aboveground biomass respectively.

By leaving the tuber in the soil, the utilization of the aboveground biomass can be done for several years. Haulm biomass ranges between 10 and 16 t DM/ha. From the second year onward, stands have to be thinned to prevent yields from decreasing. Yielding of

tuber can be done with potato harvesting technology. At the optimum stage, yields of the tuber range between 6 and 8 t DM/ha. If tuber and haulm is to be harvested, a compromise between maximizing tuber yield and the earlier maximization of haulm yield has to be found. Concerning the tuber, just as for sugar beet ensiling can be a challenge. From a cropping perspective, regrowth even from small tuber parts remaining in the soil may cause problems in the successive crop. While methane yields of haulm biomass is relatively low due to lignification (Fig. 9), the tuber can reach methane yields of up to 400 l_N/kg DM [64].

White sweet clover (*Melilotus albus*) The cropping of the biennial White Sweet Clover is currently being discussed on sites that fall below the suitability for Alfalfa or Red Clover. According to current knowledge, under Central European conditions, it can reach yields of up to 7 t DM/ha on these sites, which is around 30% lower than the comparable yield of maize. On better sites, yields of 10.1 t DM/ha were stated [65]. Additionally, an extensive fixation of nitrogen (90–150 kg/ha) and intensive and deep rooting (Root biomass of 12–18 t DM/ha) have to be included into the evaluation. On the other hand, the methane yield of below 275 l_N/kg DM is comparatively low. White sweet clover (*Melilotus albus*), which originates from Eurasia, is assessed as invasive and problematic in many parts of North America.

Rumex Originating from Ukraine, the cross of *Rumex patencia* und *R. tianschanicus* can be cultivated using standard drill technology. Utilization of cultivation material from the second cropping year can be carried out for 15–20 years in two cuts per year. Sufficient dry matter contents at the harvesting stage should be aimed at. Current results show yields of 9 t DM with low dry matter contents and hence no explicit suitability as biogas substrate [66].

Virginia Fanpetals Virginia Fanpetals (*Sida hermaphrodita*) is a perennial crop, which has little demands concerning site condition and shows strong winter hardiness [67]. On a sandy loam yields of the second and third year of cropping equaled 11 t DM/ha (Ibid.). On Eastern German loess sites, yields of the second cropping year were between 5 and 9 t DM [66] and 12 t DM [68].

Polygonum Cropping experience of the species originating from Northeast Asia is limited. Up to 25 t DM for *P. sacchalinese* can be achieved [56]. The large leaf biomass (LAI 18–25) makes stands vulnerable to hail damage. Lower yield, which is on average slightly lower than for maize, were recorded for *P. weyrichii* [69].

It should be noted that *P. sacchalinese* is closely related to *P. japonicum*. In North America and Europe, *P. japonicum* is one of the most problematic invasive species (www.issg.org). Due to the fact that *P. sacchalinese*, similar to *P. japonicum*, has an invasive root system and thus proves to be hard to control, and more so since it can hybridize with *P. japonicum*, cropping is not advisable.

Breeding (Author A. Von Felde)

In the past efforts in breeding of agricultural crops had been concentrated exclusively on progress in foodstuffs and animal feed production, mainly for the production of starch, sugar, and oil. Maximizing the production of energy with environmentally sound and resource-friendly cropping methods constitutes a new breeding goal, which expectedly will be honored by impressive results and successes within a short time. Energy maize (EM) breeding can serve as one example (Fig. 11).

Biogas Production and Energy Crops. Figure 11 Biomass yield potential of maize: Three German, one Italian, and one Peruvian maize variety (left to right) in an energy maize performance test near Wesel in 2004

The example of maize allows illustrating the enormous increase possible in biomass and therefore energy production within a short time period due to breeding efforts, if breeders do not think any more in categories typical for grain and silage use. Freed from those restrictions, new ways may be opened. Such new approaches will make it possible to increase the total dry matter (TDM) yield of maize from today's 15–18 t/ha to more than 25 t/ha. This equates to a methane output of more than 8,000 m³/ha, or a petrol equivalent of 8,000 l/ha. Figure 11 gives an impression of the biomass yield potential of maize, potential to be exploited in breeding and plant production.

The following breeding approaches may be used to increase biomass production and subsequently energy production of maize:

1. Prolongation of the phase of vegetative growth
2. Combination of late maturity and cold tolerance through breeding
3. Integration of short-day genes from exotic populations

These methods are completed by further long-term breeding goals, for example, improvement of

drought tolerance, adaptation of maize to a C₃/C₄ energy crop rotation, and adaptation of energy maize to the conditions of organic farming (by striving for robustness and competitiveness in mixed and underseed cropping).

Prolongation of the Vegetative Growth The simplified graph in Fig. 12 illustrates the reasons for which the approach of prolonging the phase of vegetative growth promises to increase the biomass potential and therefore the energy potential. The black curve (Fig. 12) depicts the course of total dry matter production of a maize variety which has been bred for silage use (SM = silage maize). The red curve shows the development of a maize variety which has been optimized for energy production through breeding (EM = energy maize).

As starch and cellulose offer the same specific methane yield, an increased vegetative growth phase of stem and leaves as such is not necessarily disadvantageous (reduced starch content).

Until the flowering of the silage maize variety, both growth curves show an identical shape. The vegetative total dry matter of both varieties increases exponentially.

Biogas Production and Energy Crops. Figure 12

Formation of total dry matter (TDM)-yield in a silage maize (SM) variety and an energy maize (EM) variety

After the flowering of the silage maize variety, however, both growth curves increasingly diverge. The silage maize's curve has a linear growth and soon flattens, while the energy maize's growth curve continues with its exponential growth. This further growth is due to the simple physiological fact that the energy maize variety continues to invest its assimilation performance in supplementary vegetative leaf mass instead of investing it in ear production, which is what happens with the silage maize variety. These supplementary leaves contribute to assimilation in the energy maize variety, while the carbohydrates stored in the silage maize variety's ears do not. This explains the superiority of the energy maize variety's yield compared to the silage maize variety's yield. The later the energy maize variety is harvested, the more pronounced its superiority compared to silage maize.

This relatively simple physiological trick of prolonging the phase of exponential growth of the plants by postponing the flowering time helps to achieve enormous increases in yield not only for maize, but as well for most of the crops.

Late Maturity and Cold Tolerance Basically, it is easy to postpone the flowering time of maize varieties.

For example, the only thing to do is to change the maturity groups cropped in Southern France, Hungary, or Italy and one immediately has breeding material at hand that flowers sufficiently late, which is what is needed for energy maize cropping in Germany.

Unfortunately, there is a big drawback regarding the breeding material groups used in such regions: They are not adapted to the cold climate and therefore do not show enough development during the early stages. All the recent hybrids from Southern European breeding programs have been tested most intensively under German as well as Dutch cropping conditions to find out whether they are suitable for energy maize hybrids. In 3 out of 4 test years, some of the Southern European varieties (and some of them even clearly) outmatched the best conventional German silage maize varieties. The only exception was the year 2004, which was extremely cold. Due to the very cold spring, practically all the Southern European varieties fell strongly behind (Fig. 13) as they had a bad initial development compared to the German silage maize varieties. In general,

Biogas Production and Energy Crops. Figure 13

The cold-tolerant German standard variety GAVOTT (on the right side) surrounded by numerous cold-sensitive Italian hybrids, photographed in July 2004 in an energy maize performance test in Wesel

this backwardness was so important that they were not able to compensate during the warmer summer months.

Therefore, breeding is called to unite late maturity and cold tolerance in energy maize hybrids. One of the obvious ways suggesting themselves is to start selecting for cold tolerance where full genetic variance is still available, which is not the level of varieties, but the level of breeding lines, which is one level earlier. At that stage, the material is not yet limited as it has not yet been checked about its ability to be combined. Figure 14 illustrates the performance of experimental crossings of 90 South European lines, which had been selected sharply. They were tested in one out of three ten times ten-lattices together with ten standards regarding their combinability with a German flint tester of a conventional silage maize breeding program. This test was carried out at Bernburg and Wesel, both German places, and also at two Dutch places. Three elite lines were tested twice together with those lines: the early German line 5G355, the medium-early French line 5F279, and the medium-late German line 5G393. The results show that it is possible to reach new yield performances of 27 t/ha with Southern European DH-lines, which have been selected for cold tolerance. This is a level that is not even reached by the presently best-performing German silage maize breeding

Biogas Production and Energy Crops. Figure 14

Dry matter yield (DM in dt/ha) as a function of the maturity of the entire plant (DM in%) of 90 new energy maize hybrids (and 10 standards) from late, Southern European lines which had been selected for cold tolerance and crossed with a German flint tester. Reference SM - Silage maize for fodder production; Reference EM - Potentiale "Energy Maize" - Breeds showing higher yield potential

material, which is represented by the three elite lines in the diagram. The late hybrids' dry matter content amounting to 30% guarantees safe ensiling without seepage and simultaneously offers good methane output. When trying to assess these results, it should be taken into account that the progress in breeding was achieved by improving just the female side of the experimental crossings, as the pollinizer used (= father) had been a line from conventional European silage maize breeding programs.

The results shown in Fig. 14 are representative for the further about 180 Southern European lines tested in the two further ten times ten-lattices with a German flint tester. They confirm the results of both previous years, where Southern European lines had been evaluated the same way, and with the same results [70, 71].

An obvious possibility is to cross Southern European lines, which had been selected previously for their cold tolerance, among themselves in order to

maybe achieve energy maize hybrids that are even more yielding. Therefore, the best Southern European lines, which had been identified in energy maize trials, were used to produce and test around 250 factorial crossings. The best performances of these hybrids reached 28 and 29 t/ha. They achieved a level of performance, which was about 7 t/ha higher than for instance the yield potential of the hybrid KXA 4163 (Fig. 15).

Integration of Short-Day Genes from Exotic Populations

There is another, and quite different, way of increasing biomass and therefore energetic performance of maize. If South American or Central American maize populations adapted to tropical short days are cropped in Central European long-day climates, those populations react with increased vegetative growth. Some of these exotic maize breeds reach heights of 4–5 m (Fig. 11). But not only the length of the stem is increased, but as well its diameter (Fig. 16).

Biogas Production and Energy Crops. Figure 15

Dry matter yield (DM in t/ha) as a function of the maturity of the entire plant (DM%) of 90 new energy maize hybrids (and 10 standards) from a factorial of late, Southern European DH-lines which had been selected for cold tolerance. Reference SM - Silage maize for fodder production; Reference EM - Potentiale “Energy Maize” - Breeds showing higher yield potential

Biogas Production and Energy Crops. Figure 16

Comparison of stems from a German, Italian, and Peruvian breed [72]

Therefore, it seems reasonable to check the effect of such genetically steered growth regulation mechanisms in an energy maize breeding program. If photoperiodic sensitivity (short-day reaction) is fixed on the female side as well as the pollinizer side of energy maize hybrids, their vegetative mass performance may be

improved considerably. Integrating such short-day genes proceeding from Mexican sources for the female side, and from Peruvian sources on the pollinizer side, guarantee, that heterosis between female and male gene pools is conserved.

In Fig. 17, the yields of 90 energy maize hybrids are shown. They contain new German–Mexican inbred lines on the female side, and a conventional flint tester from the silage maize breeding program on the pollinizer side. All of the German–Mexican inbreeds consist 75% of the German dent elite line 5G355 and 25% of gene material of Mexican origin. The superiority of the new German–Mexican inbreeds compared to the recurrent parent 5G355 is visible; they are yielding up to 10 t/ha more. This is superiority to an unexpected extent and surprising at first sight. As soon as the individual performance of the lines is checked, this increase becomes comprehensible: By selecting very sharply over several steps, it was possible to fix lines, which proved to be much more productive (Fig. 18).

Biogas Production and Energy Crops. Figure 17

Biogas Production and Energy Crops. Figure 18

New German–Mexican energy maize inbred lines (in each picture on the left side) next to conventional silage maize lines

It should be taken into account that this enormous increase in yield was achieved by improving just the genetics of the female parents of the experimental crossings. Therefore, those short-day genes should be used on the pollinizer side as well to increase the biomass potential of energy maize hybrids even more.

Outlook The outlined results demonstrate that different breeding strategies with very varied breeding material groups allow to realize enormous progresses in biomass performance and therefore in energy output of maize as an example crop. The results achieved up to now are considerably higher than expected.

The next goal of the energy maize breeding program is already defined: The considerable progresses in breeding, which could be generated up to now in the different breeding material groups, have to be united in the basic populations on which reciprocal recurrent selection is based, as well as in the hybrids. The breeding goal mentioned first (i.e., improving the total dry matter yield of maize in Central European temperate climate and stabilize it above 35 t/ha) will be reached within a short term.

The other energy plant species like sorghum, sunflower, or sugar beet have their specific breeding programs to combine most diverse genetic material to improve mass production. Energy plant breeding programs thus significantly differ from already existing standard breeding programs, as they focus on other breeding goals like energy efficiency and energy yield per hectare.

Cropping Systems

The decision on how to design cropping systems, and especially on which crop to choose, is based on the farmers' expectation of the economic gain from a specific production alternative. Apart from the natural yield capacity of a site and the revenues that can be achieved, this is determined by the crops' integration into agro-technology systems and the work organization. Importantly, the cropping structure is influenced by the existence of value-adding production capacities. These also include the biogas production.

Crop Rotation Design Rotation of crops is a basic element of crop production. The term rotation refers to the temporal follow-up of crops on one site. At the same time, the spatial juxtaposition of crops in a specific region is of special interest. Both aspects have a major influence on biodiversity, erosion by wind and water, and the appraisal of landscape characteristics; additionally, they directly influence aspects relevant to production. Extended or wide crop rotations, meaning crop rotations including a spectrum of different crops, for example, have the advantage of an increased utilization of water and nutrition reserves as well as the diminishment of weeds and pest biota.

A significant improvement of regulation possibilities, meaning the availability of plant protection products and mineral fertilizers, has led to a reduced economic importance of crop rotation design during the last century. Presently, control of nutrient supply by mineral fertilizers allows for the stabilization of yields. Yield breakdown caused by weed or pest biota can be prevented by plant protection measures. This, in combination with the tendency for specialization on a farm-scale as well as regional level has led to a narrowing of crop rotations. Presently, in Central Europe crop rotations including a high share of leaf fruits (i.e., potato, sugar beet) of 25–33% are only left common in the vicinity of starch or sugar plants.

On better production sites, cropping concentrates on winter wheat, winter rape, grain maize, and barley. In areas with best conditions for cereal production, the share of wheat can take up to 70% of the arable land, which implies a frequent self-succession of this crop. On less favorable sites, cropping concentrates on barley and rye. In regions with a concentration of livestock production, cropping concentrates on maize and barley; this – in the case of maize – can lead to a monoculture on some sites.

Energy plants can intensify this trend, for example, by extending the cropping of silage maize in livestock production areas. On the other hand, the cropping of plants that have little or no share in regional cropping systems can lead to an extension of rotations. Under present conditions, this can still imply free bonus effects, for example, cost reduction possibilities (e.g., plant protection or mineral fertilizers) or yield effects. Concerning winter wheat, depending on the fertilizing regime, the plant protection intensity and preceding

crop, yield increases of 10–50% can be achieved in comparison to a self-progression [73]. Providing for shares of sugar beet in the crop rotation can accordingly account for yield effects of 17% [74].

Furthermore, possibilities are given to productively use crops in the biogas plant, originally included into crop rotations for other reasons. Examples are the utilization of clover grass, which is primarily grown for nitrogen fixation on biological farms, or the combination of protective erosion measures by means of intercrops for their energetic use. As an overview and extension of the possible crops mentioned above, Fig. 19 shows possible options for energy cropping for anaerobic digestion and their rotational position.

Systems, which are based on the cropping of annual single main crops, either summer or winter crops, are of highest relevance in temperate climates. For energetic purposes, the cropping of a main crop is currently also tested in mixtures of species or breeds.

By adding intercrops, the vegetation time not used by the main crop can be utilized, for example, to increase annual yields for substrate production. Figure 20a and b show schematically the yield development process of winter and summer main crops with regard to solar radiation. Included into the Figure is the combination with intercrops.

Based on the approach of changing the cultivation span of the crops by shifting harvesting and sowing dates the so-called double-cropping system, including two equally productive crops, was proposed [75]. During the last years it was discussed if and on which sites a yield increase can be achieved. At the same time granting ecological advance, is one of the aims pursued by the system set-up (Fig. 20c).

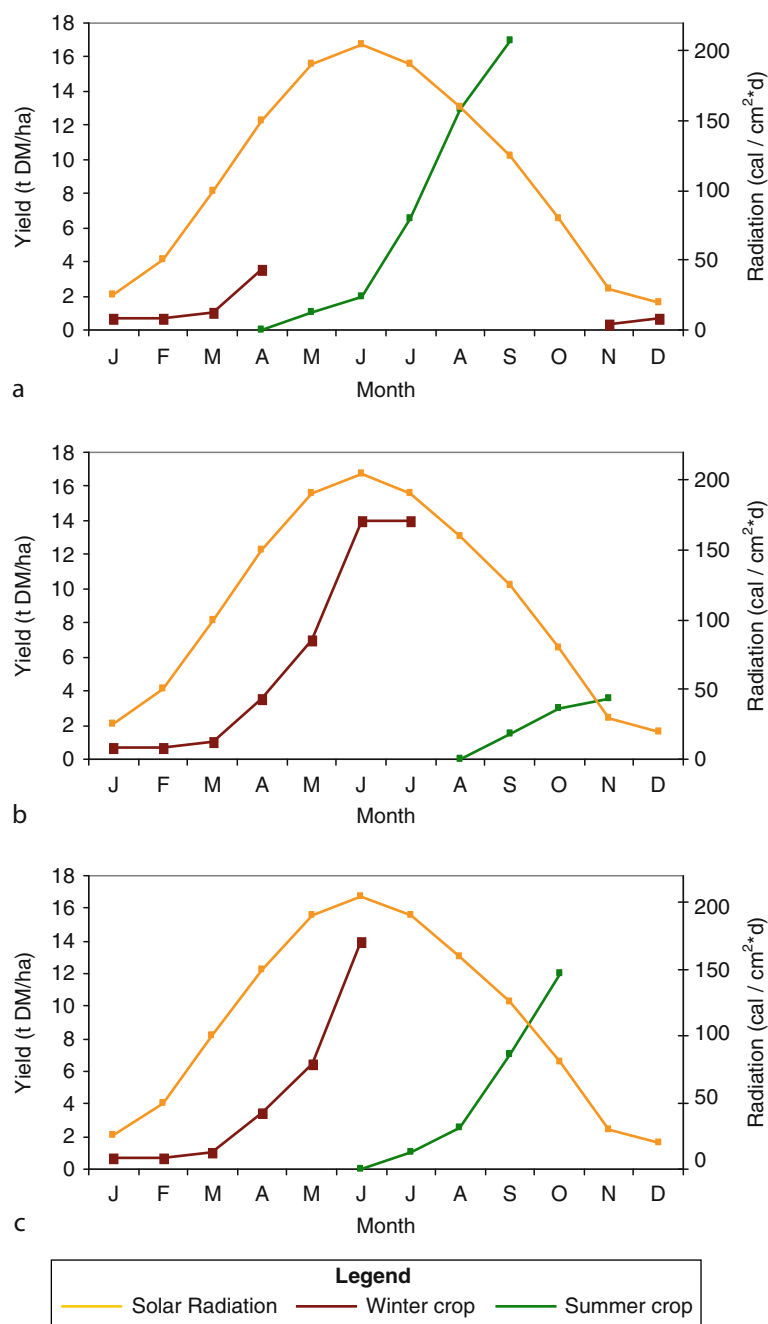

As shown in Fig. 21, various combinations exist to combine winter and summer crops. The possible time span for the change between winter and summer crop is flexible, depending on the choice of crop and the harvest stage. All in all, the time span for two crops providing similar yield amounts as shown in Fig. 20c covers a transition period of approximately 30 days. If winter intercrop and second crop (Fig. 20b) are also taken into account, the time span covers approximately 60 days.

Criteria for the possibility of yield increase by using these systems are the availability of water and the duration of the vegetation span. On soils with low field capacity, winter crops use the water reserve of the soil in spring, so without sufficient precipitation in the following period, risks for the establishment of the second crop rise. Still, even in the case of establishment success, lower water availability might reduce the yield of the summer crop, so combined yield might not be higher than the use of a single crop. On sites that

Single main crop		Double – cropping system/ Winter intercrop + second crop (including mixtures)		Perennial crops	
One crop	mixed cropping				
Sugar beet	Mixed cropping of species	Winter (inter-)crop	Second crop	< 4 years	≥ 4 years
Cereal (grain)	Maize + Sunflower	Winter rye	Maize	Clover/Grass	Cup plant
Maize	Whole plant cereals	Winter rye + w. vetch	Sweet sorghum	Alfalfa/Grass	Sida hermaphrodita
Whole plant cereal	Maize+ White sweet clover	Hairy vetch	Sorghum-Sudangrass	Grass mixture	Rumex
Sweet Sorghum	Maize + Sorghum	+ crimson clover	Summer rape	Jer. Artichoke	Polygonum
Sorghum-sudangrass	Whole plant cereal + winter pea	+ ann. Ryegrass	Sunflower		(Switchgrass)
		Grass mixture	Mustard		(Miscanthus)

show good water storage capacities (Quality wheat region, discussed later in the chapter) or sites with sandy soils but good precipitation amounts, by growing maize in combination with winter rye green

cut, a significant yield increase compared to maize as a sole crop can be achieved.

Also systems using late transition between winter and summer crop could provide surplus yields. In a 3-year

Biogas Production and Energy Crops. Figure 21
 Options for the utilization of two crops in one vegetation period

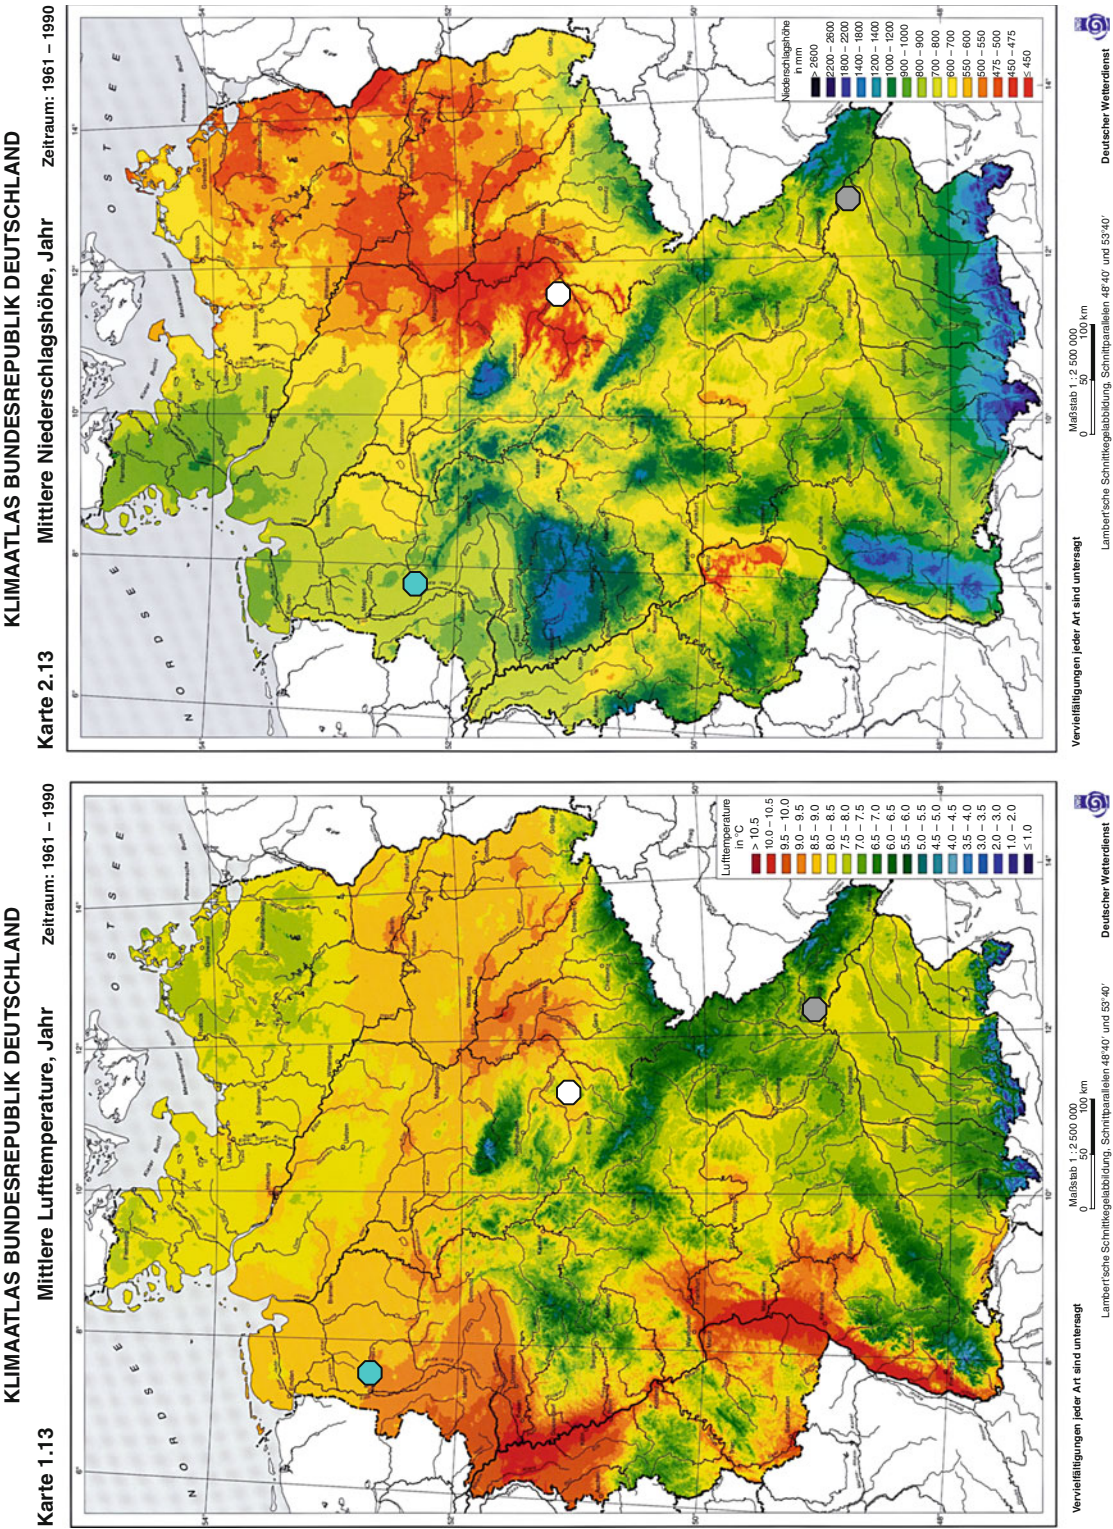

trial, a yield increase could be demonstrated for a range of different sites [76]. For the combination winter rye whole crop – maize, the comparative increase was 3.9 t DM/ha, whereas the variation in sites showed a variety of yield surplus of on average 1.9–5.8 t DM/(ha a) for a 3-year period. Under present conditions, the higher production cost for these systems in most cases exceeds benefits. For an evaluation, all free bonuses, starting from improved nutrient utilization due to all-year coverage of the soil, equalization of peak times, as well as improved ecological features should be taken into account. One of the central focus points to be set is the reaching of a sufficient dry matter yield for ensiling (see the section “[Harvest, Transport and Storage](#)”) by the second crop. An adapted choice of breeds can provide some leeway.

Regional Examples for Adapted Crop Rotations

Quality Wheat Region The quality wheat region (Fig. 22) is characterized by fairly low temperatures

(mostly 500–600 mm) and loess soils with high field capacity. Conditions are good to produce medium to high yields of quality wheat with high protein content. Within the region, livestock production is low and the share of wheat in cropping systems is very high. As a typical crop rotation, winter wheat – winter wheat – winter or spring barley – winter turnip rape can be pointed out.

Starting from this, winter cereal whole crops, for example, winter triticale can be included. Although shares of this crop are low, the yield expectations characterized are high. Exemplarily, the combination winter wheat – winter triticale WC – winter turnip rape is suitable for regional conditions. In addition, it is a cropping alternative, from an economic point of view, to the relatively unattractive winter barley. The yielding of whole-crop cereals or green-cut cereals in regions with extensive cereal cropping can also be regarded as an option to cut weeds with the crop

Biogas Production and Energy Crops. Figure 22
Annual precipitation (left) and annual temperature (right) in Germany as long-term mean (1961–1990) [77]

before the seed ripens and spreads. In this context, a significant decrease in focal weeds of plant protection has been shown [78]. A further possibility of crop rotation design for sites with a good availability of water in spring can be seen in:

winter wheat – winter rye green cut – maize
– winter wheat – sugar beet – maize

Instead of maize, for diversification and risk reduction, the cropping of sorghum is possible, too. Another option is the exchange of winter rye green cut for winter barley as a whole crop. Risks in the late establishment of maize have to be considered though. Additionally, the ripening of the summer crop as well as the trafficability of the field for the sowing of wheat should be considered.

Forage Cropping: Livestock Production Region This region of northwestern Germany (Fig. 23) is characterized by sandy soils. The maritime influence and the evenly distributed precipitation of an annual mean of more than 700 mm make good yields possible. The region is characterized by intensive livestock production and respective fodder production. The utilization of large amounts of manure for anaerobic digestion is advantageous; the problem of nutrient surplus will not be solved by anaerobic digestion though.

Due to a further increasing maize cultivation area for the purpose of biogas production in addition to fodder cropping, there is a further increased availability of nutrients; approaches focus on the increased combination of maize with intercrops. The breaking up of maize-based crop rotation, for example, by

Winter barley WC – maize – winter rye green cut – maize

can offer possibilities for increasing yields and serve further purposes such as nutrient leakage reduction and erosion mitigation due to a prolonged utilization period. Nutrient surplus in phosphorous balances in many cases limit possibilities for the utilization of fermentation residues. Therefore, approaches for the separation of fermentation

residues are currently being discussed. A much higher dry matter and phosphorous content in the solid phase allows for comparably good transportability, which makes export to sites with phosphorous demand possible. From a sustainability point of view, the decreased humus reproduction of the lacking solid phase has to be considered. From this perspective, ryegrass (mixtures) is mentioned as an alternative for the prevention of humus balance deficits and proves to be productive.

Forage grasslands – winter barley – region of German foothills and uplands

Large parts of Germany may be characterized as foothills and upland area. The conditions are, depending on altitude, relatively cool and moist. Soils are shallower and the relief is sloped. Lower temperatures make the cultivation of crops with high temperature demand or less winter hardness more difficult. Winter turnip, rape, and sugar beet are not suitable for higher regions. Maize has some importance on the more favorable foothill sites of Southern Germany. Of all the cereals, winter barley is the most important. One possibility for crop rotation design can be seen in:

Winter barley (grain) – winter triticale whole crop
– spring barley + underseed clover grass
– clover grass 2nd year – clover grass 3rd year

On farms with livestock production or possibilities for the sale of fodder, utilization of clover grass for both biogas and cattle fodder is a possible option. Hence, systems can be based on the fact that due to differing substrate demands, a (relatively observed) higher usability of the late cuts in the biogas plant can be pointed out. This is based on the higher risk of the higher contents of acetic acid, which does not, in comparison to cattle fodder production, pose a quality issue in biogas substrates.

For the design of varied crop rotations with high shares of energy plants, different crop rotations were tested in plot experiments on seven sites in various agricultural regions in Germany as part of a large cooperative project since 2005. The aim of the project is to

Biogas Production and Energy Crops. Figure 23

Cumulated yields of the uniformly tested crop rotations as a mean of all sites for the first (2005–2008) and second (2006–2009) plot set (CR = Crop rotation) [79]

evaluate which crop rotations are preferable from an economic, ecological, and plant-production point of view. On the different sites, five uniform and three to four regionally specific crop rotations were tested from 2005 to 2008 and shifted by 1 year from 2006 to 2009. Figure 23 exhibits a general overview of the mean yields on all sites of the five uniform crop rotations.

Crop rotation number 3 (maize – winter rye (green cut) – Sudan grass – whole crop winter triticale – annual ryegrass) was the most productive crop rotations on many of the sites, despite yield variations ranging from 33.6 to 56.7 t DM/ha. Sites in the regions described above could in general provide very good results. On the site of the quality wheat region, the cropping of Jerusalem artichoke and crop rotation

number 2 (Sudan grass – winter rye (green cut) – maize – winter triticale (grain usage)) could produce the highest yields, which were higher than those of a maize-monoculture. On the site representative to the forage grasslands – winter barley – region of German foothills in Ascha, relatively high yields could be provided, using a crop rotation consisting of maize – winter rye green cut – maize – winter rye/w. vetch mixture – Sorghum – Sudan grass. An explanatory approach for the high yield of this crop rotation, which is rather untypical of elevated sites, is in comparison, the higher long-term mean temperature during the experimental years with a sufficient water supply. On the site of the *forage cropping livestock production region* (Werlte), a 3-year combination of winter rye green cut and maize had a significant advantage compared to other options.

In total, the advantage of maize as a biogas substrate under a large spectrum of conditions in Central Europe could be confirmed. By also confirming the high yields of other substrates such as whole-crop cereals, sorghum, legume-grass, or grass mixtures (which can be taken into consideration in crop rotation design), complementarities could be pointed out [49].

Excursus: Factor Intensity with a Focus on Plant Protection Aspects With regard to the design of cropping systems for energy plants, altering the cropping intensity to contribute to an optimization of production systems has been discussed. On the one hand, this was related to the reduction in intensity of cropping systems by maintaining yield levels. On the other hand, questions dealt with a significant increase in yields by increasing the cropping intensity and at the same time considering sustainability issues.

Besides the above-mentioned considerations on double-cropping systems, one example for the latter is the irrigation of energy crops. In a 3-year trial, it has been pointed out that irrigation is suitable for securing a high yield level [80]. At the same time, a prognosticated climate change toward dry/hot summers and moist/mild winters in Central Europe could lead to a higher need for irrigation during summer months. Apart from the yield increase and the level of product price and the cost of irrigation, risk considerations are to be taken into account when

deciding if, where and to what extent irrigation should be implemented.

Examples for a reduction of intensity levels which can be mentioned include a reduction in cutting frequency within cultivation systems of multi-cut perennial forage mixtures, reduced tillage intensity [49], or the design of cropping systems with regard to aspects concerning factor input reduction (plant protection or fertilizer management).

In the production of whole-crop cereals, different quality requirements compared to the production of baking cereals make quality-oriented nitrogen applications for increased protein contents dispensable. A reduction in fertilizer levels below withdrawal values is noticeable much quicker than in maize though. On sites with a sufficient supply of organic nitrogen stock, maize can show better results as times of high mineralization concur with times of high nitrogen demand. In a mid-term view, a yield reduction in any crop cannot be avoided if fertilizer application is reduced below withdrawal values.

Likewise, minimal reduction possibilities can be pointed out for the reduction of plant protection measures in maize cropping in comparison to existing cropping systems. Weed control for example, is indispensable due to slow youth development of the plant. However, given the very high cropping share of maize in crop rotations and regional cropping structures the risk of problematic weeds increases (such as Crane's Bill (*Geranium L.*)). Additionally, the risk of an increased appearance of the European corn borer (*Ostrinia nubilalis*), and in some regions the Western corn rootworm (*Diabrotica virgifera*), has to be mentioned as this can lead to an increased necessity for plant protection measures.

Whole-crop cereals differ from cereals harvested for grain purpose with regard to the cropping span. Risks of ear infection, pest biota, and weed problems are therefore comparatively lower. Depending on the type of cereal, breed and site characteristics, and yield expectancy accordingly, plant stability may be sufficient to dispense with growth regulators. This is the case primarily on dry and low-yielding sites and for winter triticale and winter barley. On productive sites, growth regulators should not be dispensed with. Turning down fungicides can result in a decrease in yield. Under the

conditions of the quality wheat region, in most cases, reduced benefits are lower than the economic cost for treatment [81]. On sites with low weed pressure, the comparatively high competitive strength of whole plant cereals can provide possibilities for the reduction of herbicide measures.

In a broader perspective on entire farming systems, anaerobic digestion may also provide possibilities to utilize lots for conventional grain/seed production with heavy pest or weed infestation in biogas plants. Importantly, it was questionable if pest biota or weed seeds can outlast the biogas process and lead to higher infection/weed pressures when recirculating fermentation residues to the field.

According to [82], preliminary results are available for 14 phytopathogens involving relevant quarantine diseases of potato. Following these results, most pathogens cannot persist in digesters working in mesophilic conditions under common retention times. Only *Clavibacter michiganensis* subsp. *sepedonicus* shows a viability of more than 100 days. When supplying entire potato tubers, *Ralstonia solanacearum* could persist for 30 days in a batch experiment. According to this, a retention time span from practical biogas plants could be sufficient to provide the required sanitizing environment. *Xantomonas translucens* pv. *graminis* survived the process for 26 days. After 6 days however, infectiousness stopped. Additionally, it should be pointed out that ensiling might already kill pathogens before anaerobic digestion.

Of high relevance for intensive cereal cropping regions is the statement that the decomposition of *Fusarium graminearum* could be observed after 1 day [82]. This confirms results from [83], which, in addition, point out the disintegration of mycotoxins.

Survival of the seeds of some weed species is possible and continues to be the focus of research activities. One of the key parameters appears to be the temperature level of the biogas plant. In thermophilic conditions, seeds of blackgrass (*Alopecurus myosuroides*), goosefoot (*Chenopodium album*), stinkweed (*Thlaspi arvense*), broad-leaved dock (*Rumex obtusifolius*), and wild mustard (*Sinapis arvensis*) lose their ability to germinate after a retention time of 24 h. In mesophilic conditions, this only applies to blackgrass and wild mustard. Goosefoot had a germination ability of 75%. The durability of the testa against microorganisms could

play a major role. Seeds of goosefoot, black-bindweed (*Polygonum convolvulus*), and cockspur (*Echinochloa crus-galli*), which proved to be unable to germinate on agar, were still found to be viable in a Tetrazolium test [84]. Further results on the topic are awaited.

Harvest, Transport, and Storage

The bridging of the spatiotemporal difference between yielding of the crop at the optimum time on the field and the feedstock requirements in the digester make an optimized planning of harvesting procedure, transport, and storage of a specific substrate necessary. The specific challenges of supplying sugar beet are described in the section “[Production Systems of Sugar Beet](#)”.

Harvest and Transport Harvest date of the chosen crop type and breed is primarily oriented according to the maximum yield and substrate quality, but also according to the inclusion into crop rotations and work organization of the farming company. With regard to these factors, time frames for harvesting are determined for the different crops.

Most crops can reach the dry matter contents necessary for ensiling (see below), so harvest procedure can be single-stepped. For Grasses and green-cut cereals with low dry matter contents, the cutting can be done as a separate step, after which a phase of wilting is followed up, needing a period of 1–2 days of suitable weather conditions. When reaching optimum dry matter contents, swathed material is picked up by a chopper. Compared to sufficiently dry substrates, which are directly harvested, additional losses have to be calculated with.

Standard operation system for harvest and transport is the chopping chain. A central element is the utilization of a self-propelled forage harvester; to some extent is also that of tractor-mounted choppers. Capacities of forage harvesters sold on the market are in the range of up to 1,000 HP effective output. Depending on the substrate to be harvested/picked up, harvesters can be fitted with different harvesting units. One of the most important parameters for an economic operation is the throughput rate (Harvested Mass times Working Speed). In the forage harvesters currently available, depending on the installed engine

power, this can be equal to up to 300 t of fresh matter per hour.

For an optimized anaerobic digestion, chopping size is an important parameter. In batch tests, maize, which was chopped to an average size of 4.7–5.4 mm showed 8% higher methane yields per t DM than maize with average chopping sizes of 7.9–9.9 mm [85]. With increased lignification, finer chopping, which can be characterized as mechanical pretreatment, makes an even higher percentage of methane yield increase probable [85–87]. Short chopping sizes lead to a loss of efficiency and higher diesel demand during chopping operation – therefore an economic optimum is to be aimed for. For an efficient design of operation procedures, a continuous transport from the field is to be vouched for. Most commonly, a parallel operation procedure is used in which changing transport units (consisting of tractor and transport hanger) move besides the harvesting unit and transport the feedstock to the silo. The loading mass is influenced by the bulk density of the substrate. Even with an optimized design of the operation procedure, cost is significantly increasing with transport distance. The cost increases disproportionately (Fig. 24) [88, 89]. Low dry matter contents also have an effect on transport cost per dry matter (and energy yielded).

Storage To ensure continuous feeding of the plant with seasonally harvested material, the process of ensiling is used. For this, the substrate is compacted, with the goal of appropriately excluding air to ensure that the lactic acid fermentation process is optimized. In this type of fermentation, carbohydrates from plant material are converted into acids, which have a conserving influence. The conversion processes of ensiling involve an unavoidable loss of energy and matter. The overall losses, which might also involve noxious fermentation, seepage sap losses, and aerobic deterioration during storage and withdrawal, can be minimized, though [90]. The specific challenges in conserving root and tuber substrates which show little ensiling quality is dealt with exemplarily in the section “Sugar Beet”. A high share of usable carbohydrates and a sufficient number of suitable microorganisms on the plant material has a positive influence on the process. A high share of proteins and minerals (buffer) leads to the bonding of acids, which reduces the ability to lower pH-values. The deciding criterion for the design of cropping systems is the achievement of dry matter contents favorable for ensiling processes. Depending on the substrate type, values of at least 28% should be aimed at. Substrates significantly lower in dry matter content have a lower

Biogas Production and Energy Crops. Figure 24

Specific harvesting cost of maize from a 5 ha-plot as a function of transport distance [88, 89]

suitability for ensiling and depending on the height of the substrate in the silo, big quantities of seepage sap can leak from the silo. These quantities are to be used in the biogas plant. Dry material (>35% dry matter content) is much harder to be compacted, so risks for large losses from aerobic deterioration are increasing. With regard to overall losses in this step of the process due to insufficient ensiling qualities, up to 31% decreased methane yield in comparison to laboratory-scale ensiling has been found [91].

Losses that occur in form of carbon dioxide, hydrogen, nitrogen oxides, or ammonia are unavoidable though. The inevitable losses by final respiration processes and the activity of fermentation organisms are at least 5% of the net energy in the plant material [21]. In addition, losses occur by incomplete exclusion of air in boundary areas and aerobic conditions at times of withdrawing the substrate. Additional losses of at least 3% of the net energy can be expected. Biological or chemical silage additives can be added to the substrate to avoid large silage losses. It should be noted that by using biological silage additives, which are based on homo- and heterofermentative lactic acid bacteria, an increased amount of acetic acid might be formed [92]. While this is a negative aspect for the quality assessment of silages used for fodder, in the process of biogas formation, acetic acid has no negative influence.

Considering the requirements for a loss-minimizing ensiling process, the silages can be stored for a longer period of time [93]. Despite the higher cost for storage space, this gives leeway for substrate provision. In laboratory-scale experiments, losses of silages stored for 365 days were increased by 1.2–6.4%

compared to silages with a short storage period. The tendency of increased gas formation potential of the longer stored silages could compensate for the losses though.

Utilization of Fermentation Residues

Production systems for anaerobic digestion are specifically characterized by the fact that fermentation residues can be recirculated as organic fertilizer. After the digestion process in the plant as shown in Fig. 8, barely digestible substances are still in their original structure. Substance groups with good digestibility are largely mineralized to soluble inorganic compounds.

Due to the fact that only little substance losses occur (e.g., in the process of ensiling, see above), and that nutrients in the residues are – in comparison to those in feedstock before digestion – by far more available to plant uptake, biogas systems are suitable to design largely closed nutrient cycles.

A factor in the evaluation of nutrient cycles, which also has to be taken into account, is that only few biogas plants only use plant material for digestion. In fact, anaerobic digestion is very suitable to utilize excreta from animal production. Mass flows, which in many cases include nutrient input by imported fodder, also have to be taken into account.

Analysis of the fermentation of different biogas plants fed with dedicated energy crops and carried out at different times show the large variety of nutrient levels (dependent on substrate input, pretreatment, and digestion rates) in fermentation residues (Table 4).

Biogas Production and Energy Crops. Table 4 Dry matter and nutrient contents as well as pH values of fermentation residues exemplarily in central (Thuringia) and south-western Germany (Baden-Württemberg) [93, 94]

		TM%	pH	N _{ges}	NH ₄ -N	P ₂ O ₅	K ₂ O	MgO	CaO	S
Baden-Württemberg N = 102	Mean	7.0	8.3	4.7	2.7	1.8	5.0	0.84	2.1	0.33
	80%-qrtl.	5.0	7.9	3.9	2.1	1.2	3.8	0.47	1.5	0.26
	20% qrtl.	8.5	8.6	5.5	3.3	2.1	5.5	1.04	2.6	0.41
Thüringen N = 60	Mean	5.8	7.7	4.2	3.1	1.8	3.4	n.v.	n.v.	0.04

Compared to animal manure, the relatively close relation of C/N in fermentation residues is to be mentioned. This leads to a decreased immobilization of the nitrogen included in the fermentation residues [95]. Due to the comparably high contents of ammonium, nitrogen is also present in a form well available for plant growth. Depending on the crop type, recommendations are to calculate 60–80% of the total nitrogen in the fermentation residues as equivalent to mineral fertilizer [94, 97]. In summer crops, in comparison to winter crops, higher percentages can be taken into account. Values for mineral fertilizer equivalents of 77% for maize and 86% for spring wheat have been shown [96]. Phosphorous and potassium can almost completely be recycled [97].

The release of calcium in anaerobic digestion leads to higher pH-values compared to animal manure, which is not utilized in biogas processes. Whether higher values for ammonia emissions occur, is in discussion. Fermentation residues have a relatively low viscosity, which leads to better handling (homogenization, pumpability, etc.) and soil-infiltration properties. This leads to the fact that the higher emission risk due to increased pH-values can be compensated for [96]. In any case, loss-minimizing technologies as well as an immediate incorporation into the soil are means of avoiding ammonia losses. These can be minimized, but not completely eliminated.

The usability of a relatively good fertilizer and a saving of mineral fertilizers (in comparison to grain/seed production systems) have to be considered when evaluating biogas systems. It should also be noted that in regions with high nutrient input by fodder imports and an increased cycling of nutrients, nutrient balances, for example, of phosphorous, can be limiting due to maxima set by legislation. Solutions, such as the separation of liquid and solid parts of the residue are currently under discussion. Different technical approaches to the separation have in common that both phases have a different nutrient content. The liquid phase is higher in NH_4 -content related to total N-content, but has a smaller phosphorous content. The solid phase can include up to 70% of total phosphorous. It is more transportable and can be exported into regions with a phosphorous demand [98].

From an economic and an ecological point of view, the utilization of nutrients in the fermentation residues should be in the most efficient manner. Rules of “good agricultural practice” as well as binding legal regulations are to be followed. These include:

- Limiting the fertilization span on times in which nutrients can be used by crops
- Knowledge of plant demand and nutrient contents of the fertilizer
- Limiting the quantities and area balances accordingly
- Specification on the storage of residues
- Specification of the loss-minimizing deployment technique
- Extended requirements in the utilization of waste material, for example, contagion hygiene requirements

Already during the planning phase of biogas plants, the management of fermentation residues should be involved. Especially in large plants, the low transportability of the fermentation residues should be considered. Optimized fertilizing strategies require efficient deployment logistics, especially in times where deployment makes a maximum uptake of nutrients by plant growth possible.

Sustainability Aspects

For a long time, sustainable management has been a basic principle of agricultural production. As part of this production, the cultivation of dedicated energy crops is therefore underlying the rules and guiding principles of “good agricultural practice” in addition to Cross Compliance requirements and further regulatory and prohibitive instruments. The increased production of dedicated energy crops and the associated support programs were linked to public institutions formulating further goals that aim at an increased contribution of energy cropping toward a sustainable design of energy and land use systems. Central aims are to contribute to greenhouse gas mitigation and environmental protection, as well as saving fossil fuels and decreasing the cost of energy supply also with regard to external costs and technology development [3]. Furthermore political aims are targeted at safeguarding the energy supply, preserving

biodiversity and soil fertility, and contributing to employment and value creation especially in rural areas [99].

Depending on the weighting of the different target values, differing assertions and deductions toward the design of agricultural systems can be drawn. Additionally aggravating is the fact, that quantitative and comparable evaluation categories can sometimes be barely defined and controlled for a number of targets. Accordingly, for the quantitative approach of life cycle assessment, in addition to the definition of a reasonable “balance scope,” for the evaluation of target values, a subjective value system has to be referred to [100].

Green House Gas Balance

Based on the fixation of carbon dioxide by photosynthetic processes and the utilization of the fixed carbon to substitute fossil fuels, agricultural production can contribute to climate gas mitigation. Furthermore, the anaerobic digestion of excrements can also contribute to the reduction of emissions caused by other fields of agricultural production. To estimate to what extent the utilization of dedicated energy crops can contribute to a mitigation of climate gas emissions, the net climate gas reduction is to be calculated. Basically, this is determined by the balance of reduced emissions due to substituted fossil energy sources and the sum of emissions in the production system.

Emissions in the production system are not only determined by the factor input (fuel and fertilizer production) for cultivation steps, but also by climate gases emitted in substance cycles such as methane and nitrous oxide. Influence on the emission of methane is provided by mitigation potentials during the utilization of excrements. Otherwise, risks of methane emissions during the process of anaerobic digestion and utilization of the gas have to be mentioned. The largest emissions that are relevant to climate warming from soils are those of nitrogen compounds, which are linked to the utilization of mineral and organic nitrogen fertilizers.

For the evaluation of climate gas mitigation in the cultivation of renewable raw materials, a range of values can be looked at. Apart from the overall emissions that are avoided by the substitution of fossil fuels by biogas, these are mainly evaluation values for a specified area

(kg CO₂-eq/ha) or product quantity (kg CO₂/GJ) as well as the associated cost. Furthermore, when looking at evaluation values, the subdivision into avoidable and unavoidable emissions is helpful.

Output and Substitution Values Decisive values for energy and climate gas balances are the methane yields of the different crops and crop rotations per unit of area. High hectare yields provide the possibility to substitute high amounts of fossil fuels. Relative indices, which give (energy) input in relation to output, often have the weakness of not considering the area as the scarcest factor.

Extensive production can lead to a reduction of energy-related factor usage and emissions. However, a thorough risk evaluation should be done, when assessing minimization strategies as well. An extreme example can be seen in the waiving of plant protection measures in the cropping of maize – yield loss and the respectively lowered energy gain will overcompensate the reduction in energy input by several times [101].

For a further evaluation of greenhouse gas savings potential, the reference base for example, the emissions of the substituted energy also plays a major role. Highest greenhouse gas reduction potentials can to be seen in the substitution of electricity produced from coal (e.g., lignite). Against this assumption, assuming a flexible electricity production with biogas substituting natural gas-driven peak load power stations leads to lower greenhouse gas savings.

Primary and Secondary Emission Values Primarily relevant to greenhouse gas emissions are factor inputs for the working processes that are necessary for the establishment, fostering, and harvest of a crop. These are most importantly not only fuels, but also fertilizer and plant protection products. Energy- and material-related emission values for provision of machinery and maintenance should be accounted for as well.

Of high importance is the kind of tillage system used. Minimum-tillage-systems waiving the usage of plowing measures have an advantage because of less fuel demand. Furthermore, the distance of the field from the biogas plant is relevant, since large parts of the energy have to be used for transporting processes. Values for conventional

plowing systems and a transport distance of 6 km have been calculated. For a Thuringian site, for example, these add up to between 58.9 l/ha (sorghum) and 82.9 l/ha (maize) [102].

Fertilizing can be regarded as the quantitatively most relevant part of emissions. Firstly, this is due to the energy-intensive production of mineral fertilizers. Because of the possibility to efficiently recirculate nutrients in biogas production systems, in comparison to market crops bonuses (when used in other crops) or reduced mineral fertilizer input have to be taken into account, though.

Secondly, secondary emissions from production-related nutrient cycles have to be considered. Of high relevance are the emissions of nitrogen compounds (most importantly nitrous oxide) emitted in the course of nitrification and denitrification processes. The emissions of this gas are relatively small quantitatively; though with a high radiative forcing, they make up

a large part of climate gas emissions of intensive cropping systems.

Figure 25 shows the resulting climate gas emissions for the production of one kWh of methane that can be attributed to energy cropping systems on different sites in Germany.

Shown as white columns are the balances of emissions and bonuses which have been taken into account by the recirculation of residues (green). The relatively low values for maize can be explained by the good yield (and energy gain accordingly) in relation to the input and according emissions. The combination green-cut rye and sorghum on the dry and sandy site Güterfelde leads to the highest emissions, which can be explained by the relatively low yields at this site. With regard to the high share of emissions in the field of fertilizing, the nitrogen efficiency, and therefore, the nitrogen input per unit of product (in this case methane) is of outstanding importance. In this context, it should be

Biogas Production and Energy Crops. Figure 25

Resulting climate gas balances for different options of cropping of energy plants on different sites in Germany [102]

mentioned that the values used in Fig. 17 are calculated on the base of standard values proposed by IPCC, who recommend a calculation involving the emission of 1% of fertilized nitrogen as nitrous oxide.

For the specification of this simplified quantitative interrelation, as well as for the closer characterization of the “new” fertilizer fermentation residues, several research projects are currently ongoing. One thing that can already be stated is that the processes of nitrification and denitrification, which are the base of nitrous oxide emissions, are based on the insufficient utilization of nitrogen rather than the total amount of fertilized nitrogen [103]. Additionally, the availability of oxygen during the alteration processes of nitrogen compounds is of high relevance. On soils with high contents of clay and a nitrogen utilization of less than 30%, the emission of nitrous oxide is increasing disproportionally [104]; nitrous oxide emission also increases considerably on water-saturated soils emissions after organic fertilizing [105]. Furthermore, the frost–thaw cycles during winter seasons in temperate climates lead to large quantities of nitrous oxide emissions. These emissions are unavoidable, but can be

minimized by an optimized fertilizer application in spring and an optimized plant uptake before winter takes place. Influence on emissions of nitrous oxide and ammonia also can be taken by an optimized fertilizer application technology (Fig. 26).

From a technological point of view, the splash plate is obsolescent. Injector technology is largely avoiding ammonia emissions, but this leads to the highest emissions of nitrous oxide [107]. Ultimately, a target conflict between minimizing emissions of ammonia and nitrous oxide can be pointed out.

Clearly, nitrogen fertilizing should always aim at an optimized utilization within the entire system. An optimized adaptation of crop rotations under consideration of intercrops, in addition to the efficient inclusion of maize into market cereal crop rotations, can promote a more efficient usage of nitrogen within the farming system. As an example, for an extension of the crop rotation of a cereal-oriented farm by producing biogas and selling straw a clear reduction of overall nitrogen surplus is achieved [107]. This example also points out that not only is the reference system of substituted energy form, but the reference system of alternatively

Biogas Production and Energy Crops. Figure 26

Influence of spreading technique for fermentation residues on resulting emissions (Shown in CO₂-equivalents) [106]

stated usage of the arable land is of major importance for evaluation of ecological impacts.

In conclusion, on the field of optimized organic fertilizing with fermentation residues, there is still a demand for further research. From a practical agriculture standpoint, research should point out possibilities to optimize the utilization of nutrients in the fermentation residues; from a sustainability point of view, on the other side of that same coin, the minimization of nitrogen losses should be strived for.

Humus Balance and Preservation of Soil Fertility

As mentioned in the section “[Soil and Nutrient Supply](#)”, organic substances in agricultural soils play a major role for nutrient storage and transformation processes. Furthermore, on a global scale, organic substances in soil serve as an important carbon sink. Contents of carbon and humus are not identical, though. In most cases, the carbon content (C_t) multiplied by the factor 1.706 equals the humus content. In soils containing carbonate, the share of inorganic carbon has to additionally be taken into account.

The dynamic character of trans- and deformation processes of organic substances in soils makes it necessary to perpetually supply soils with organic matter, in the appropriate amount of the microbial disintegration to mineral substances, in order to sustain the level of soil organic matter content. Therefore disintegration rates are of interest. These are influenced by climate, nutrient supply, soil structure as well as the tillage system used.

Major sources of supply for organic substances are roots and harvest residues. Crops can accordingly be differentiated into humus-diminishing crops (e.g., sugar beet) or humus-increasing crops (e.g., perennial grasses). Furthermore, the supply of additional aboveground biomass such as straw and the recirculation of organic fertilizers are important sources for soil organic carbon.

In energy plant production, which aims at a utilization of total aboveground biomass, only little harvest residues are left on the field in comparison to, for example, the production of cereals for grain usage. By recirculating fermentation residues, large quantities

of carbon-rich substances, which could not be disintegrated in the process of anaerobic digestion, are resupplied to the soil, though.

Distinct changes in the humus content of soils can only be observed within longer periods of time. In this context, it should be noticed that depending on site characteristics and the chosen management system, only in the long-term specific humus content is materializing. To be able to evaluate these processes quantitatively, several models exist that provide reference values for humus formation and decomposition derived from long-term tests.

Such models are the VDLUFA-Method, the Repro-Method and the Site-adapted Balancing Method [108]. All methods differentiate between the cultivated crops. Exemplarily, the VDLUFA-Method exhibits an annual humus decomposition for maize of between 560 Humus-C ha⁻¹ (on soils showing a good state of cultivation with optimum mineral fertilizing) and 800 kg Humus-C ha⁻¹ (on soils which have been poorly supplied with humus for a longer time and soils under ecological management practices) (Table 5).

A calculation of humus balances of cropping systems for rotations including a high share of energy plants shows that except for the rotation which includes a perennial forage mixture, a cropping without recirculation of residues would lead to a decreasing humus content in soils and hence a decreasing soil fertility on Central European sites (for a description of the crop rotations see Fig. 24). This should be considered, for example, in concepts for fuel production (Biomass to Liquid, BtL) which, in contrast to biogas production, do not allow for a recirculation of residues which contribute to a supply of organic matter.

As can be seen on the right part of Fig. 27 a recirculation can lead to a much better supply of humus in the tested crop rotations, when considering the recirculation of residues. In crop rotations with a high share of perennial forage mixtures (CR 4), the recirculation of organic matter causes balances which bring about the risk of high and uncontrollable mineralization. For the calculation, a humus reproduction rate of 0.3 for the fermentation residues was estimated. The reproduction rate describes the

Biogas Production and Energy Crops. Table 5 Change of Humus-Carbon dependent on specific cropping in various energy crops ([109] according to data from the EVA-project)

Crop	DM-yield (tha ⁻¹)	Specific change of Humus-C	
		Dynamic HE-method [110, 111] (kg ha ⁻¹)	VDLUFA [112] Lower value to Upper value (kg ha ⁻¹)
Whole-crop cereal	8.1	−595	−280 to −400
Silage maize	17.6	−969	−560 to −800
Sorghum (bicolor × sudanense)	12.3	−609	
Sorghum (bicolor × bicolor)	9.0	−592	
Rye (green-cut intercrop)	4.8	87	120 to 160
Annual ryegrass (summer intercrop)	3.7	81	100 to 150
Clover/Alfalfa grass (Main utilization year)	10.9	829	600 to 800

Biogas Production and Energy Crops. Figure 27

The dots indicate the median; error bars indicate the span of tested sites [109]

amount of carbon in the residues that can be regarded as effective for humus formation. The scientific discourse on the definition of scientifically secured values is not terminated yet [110, 113–115].

Biodiversity

The increased cropping of energy crops is falling into a time in which a preceding reduction of biodiversity in Europe has been observed (e.g., [116]). Model-based

evaluations, which attribute negative impacts for energy plant production (e.g., [117, 118]), often have the weakness that they do not allow for a differentiated analysis of cropping techniques. Other approaches focusing on this aspect could – in the analysis of different cropping systems – point out that the different energy plants that can be used can provide habitat for a variety of wild-living species.

To answer the question on what impact can be expected from an extended energy plant production,

not only the chosen energy plant species has to be regarded. More importantly, each plant in its spatial context has to be analyzed. This means that besides the habitat conditions during the course of management and the development of the crop stand itself, the neighboring structures have to be taken into account.

The most important finding is that, in a cultural landscape, each crop can contribute to biodiversity, depending on the grade of differentiation from the other crops under cultivation regarding its characteristics such as cropping time span, horizontal and vertical vegetation structure or flowering. The more diverse a regional cropping structure, the higher the probability that wild-living species can find suitable habitat conditions. This effect is demonstrated for plant species and fauna (ground beetles, spiders, and apidae/syphidae) (Fig. 28) [78].

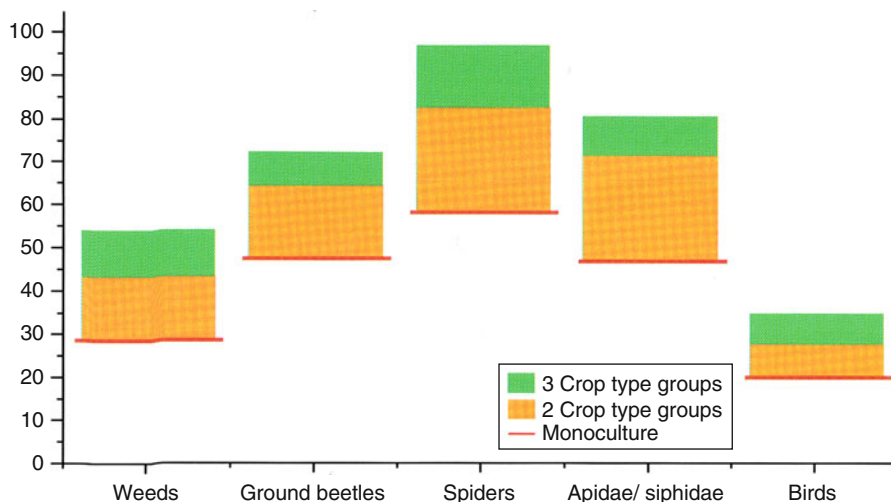

The Figure shows the number of species occurring, depending on the number of crops in the crop rotation. The number of individuals of the different species or the level of coverage of weed species/side flora is not increasing parallel to the number of species. It can rather be quantified by the mean of the individuals that can be observed in the single crops. If the number of crops in a rotation is reduced down to monocultures, the species number is reduced, too. The danger of

the prevalence of single organism types is increasing significantly [78].

Positive impacts on the species number of most organism groups can be expected by an increased cropping of perennial crops. As an example, the cropping of perennial forage crops provides habitats for species that can only seldom be found in other crops. Examples of such species include species whose occurrence is dependent on a period of resting soil for several years such as grasses in general, rhizomatic species and hemikryptophytes and when regarding fauna, species that are active throughout the whole year, such as some spiders and some apidae/syphidae are notable examples. Perennial forage crops also provide hibernation possibilities which other crops lack [119].

Multi-cut perennial forage crops might also become a trap for some species, since high cutting frequencies and especially the first cuts in spring times might lead to a destruction of the clutches of ground-nesting birds [120]. The same applies to whole-crop cereals that are harvested earlier than cereals produced for grain use.

On the other hand, the combination of whole-crop cereals harvested comparably early with second crops, as described above (double-cropping system, Fig. 20c), can lead to a prolonged habitat utilization period for

Biogas Production and Energy Crops. Figure 28

Species number of different organism groups in crop rotations containing high shares of energy plants depending on the number of crops included into rotation systems. Base EVA-Project (Data from Thuringia, Bavaria, Mecklenburg-Pommern for 2005–2007.) Values for birds are based on a consultation of experts and are inflated by a factor of 10 [78]

the different organism groups. Another example, for land use change leading to a multitude of effects that are positive and negative for biodiversity, is the fact that early cuts might lead to a decreased spreading of weeds. For example, 35% of flowering plants occurring in winter cereal stands and 25% of flowering plants in spring cereals do not reach seed ripeness in the case of whole plant harvest [78]. From the viewpoint of the farmer, this might be an option for weed regulation and the minimization of herbicide treatments, especially when taking the multiresistance of some weed species into account.

A differentiated view on the impact of different crops can be observed in the occurrence of flower-visiting animals. While winter wheat provides good conditions for the occurrence of solitary bees, bumblebees and hover flies are rather to be found in maize. Depending on the importance set on the occurrence of organisms, the evaluation of different energy crops is therefore variable. In the end, the evaluation of the impacts of feedstock production for anaerobic digestion on biodiversity amounts to the question, if the energy plant production with its various options results in an extended variety in cropping structures or if in a mid-term perspective, no such extension will be the case. For an evaluation of the different options, regional cropping structures should be taken into account. The fact that an extended cropping of silage maize is not necessarily leading to a reduction, can be shown at the cropping structure of the “Saale-Holzland-Kreis” as part of the “Quality wheat region” mentioned above. The cropping for silage maize in 2007 was less than a quarter of the area for winter cereals. An extension of the maize cropping area would therefore be linked to an increased biodiversity in organisms, whose population development takes place in late summer, for example, summer-flowering plants, as part of the flora, or ground beetles larvally hibernating as well as summer-active spiders and syrphidae.

Future Directions

The utilization of energy plants for biogas production provides chances for a sustainable provision of quantities of substrate which are not available from other sources. Solar radiation that is saved in the substance

groups of biomass can, in the following utilization chain, be stored and, after anaerobic fermentation processes, be used in the form of methane. The utilization chain allows for a steady-going electrification or the upgrading of biogas for the feeding in of methane into the gas grid.

The particularity of biomass production for energy purposes is the fact that it is always part of the existing agrarian (eco-)systems and can therefore complement these. Chances therefore exist that biomass production can be seen as a structuring element, which can provide chances for farming income diversification, extension of crop rotations, risk diversification, and the equaling out of work peaks as well as for sustainability targets such as biodiversity and climate gas mitigation.

As for future directions, it becomes obvious that the extension of biomass production is not leading to the achievement of the variety of the different goals per se. In fact, the application of sustainable farming options for biomass production and the achievement of societal goals are also linked to the question, to what extent the application of these systems is interesting from the economic point of view of farming practice. Since in most cases energy farming is dependent on public subsidies, the challenging task is resulting to design mechanisms that in the context of volatile markets for agricultural goods can keep planning security and the long-term character of targets in focus and avoid bringing forward systems that are based on the pursuance of one-sided and short-term goals.

Definition of the Subject

Energy is essential for human development. Without an adequate basic energy supply, people cannot cook their food, light their homes, or keep food and drinks chilled for storage. Alongside the introduction of efficient and clean thermal use of waste biomass for

cooking, the provision of electricity from renewable energy sources can provide basic energy services for lighting and communication and promote local economic growth.

Biogas-producing (anaerobic) treatment units as part of an integrated waste-to-energy treatment system are an alternative to use waste biomass as feedstock due to their energy and soil conditioner production capacity, low-tech components, and adaptability. It is also an excellent technology for treatment and reuse of manure and straw, organic sludge treatment collected from septic tanks, holding tanks, dry toilets, or for organically loaded wastewater pretreatment.

Decentralized low-tech biogas system solution provides a unique possibility for promoting appropriate household and community scale solutions to social and environmental problems; it is apparent that worldwide still many people are seeking friendly, small scale solutions for themselves and their communities, including biogas systems with lower specific performance efficiency, but out-balanced with lower degree of system mechanization and larger construction volumes.

Several research institutions and international agencies rate biomass as one of the cheapest available renewable energy sources for heat and power generation. Furthermore, conversion from biomass to useable energy is a low-carbon process as the resulting CO₂ is captured by plant regrowth. In contrast to other renewable energies, biomass energy conversion technology can generate heat and power on demand at flexible time, as long as a sufficient supply of feedstock is assured. Many municipal, agricultural, and livestock residues can provide feedstock for bioenergy conversion without increasing land requirements.

The main advantages of the anaerobic treatment process compared to the aerobic treatment process are the generation of biogas and significantly less sludge production. The fact that the plant nutrients phosphorus and potassium are not removed in the treatment process can also be an advantage for the application of the effluent in agriculture to replace chemical fertilizer, but the final effluent should never be discharged directly into water bodies without further treatment, unless the carrying capacity of the receiving water body is not exceeded.

Often industrialized countries neither have sufficient experience nor appropriate technologies to build on in developing countries. Transferable experience in low-tech biogas systems was identified in 1978 first in India and China and transmitted initially by a South-North-South transfer during 1980–1993 by international development cooperations. In the first decade, biogas technology focused on small-scale farmers. At a later stage, also larger farms as well as waste treatment issues increasingly became the additional focus of biogas technology. The term “appropriate technology” seemed justified by the fact that low-tech biogas systems are still adapted to the respective local conditions during a “learning-with-developing-countries” process.

Introduction and Development History

The topic “biogas” is relevant to all areas of rural development. Often overlooked, biomass is the most important renewable energy source in developing countries. Nearly one third of the world population cooks on open fires or traditional stoves with biomass (like wood, dung, straw, and agricultural waste). When cooking on biomass in huts, without chimney, flue gas causes significant respiratory and eye disorders. Therefore, the use of chimney-connected wood-saving stoves and biogas as clean cooking fuel is indispensable for improving health of women and children.

Inadequate sanitation in developing countries is a big issue. Moreover, manure, slaughterhouse waste, and untreated sewage pose major problems to health and environment. To use the energy potential of wastewater and waste, these organic substances can be treated in anaerobic (biogas) plants. The biogas produced can be used for cooking, lighting, heating, and cooling, and – if sufficient – to run engines. As a by-product, a valuable organic fertilizer is produced. Biogas plants therefore provide not only advantages for environment and sanitation, often, the most important aspect is the localized energy production and supply with biogas.

Due to the increasing awareness on climate change impacts, eco-friendly renewable energies are nowadays more in demand than ever. In relation to

these changing conditions and technical developments, biogas as a greenhouse gas neutral source of energy is an often-discussed topic in developing countries.

There are different expressions used for the same technology: anaerobic digestion, biogas plants, anaerobic fermentation, and biogas-sanitation system. The technology has been used for excreta treatment now for more than 100 years; thus, biogas is for sure the oldest “modern” renewable energy. Anecdotal evidence indicates that combustible natural gas (obviously natural gas, or marsh gas from swamps) was used for heating bath water in Assyria during the tenth century BC and in Persia during the sixteenth century BC. The science of anaerobic digestion is as old as scientific research can be and includes the names of world’s most famous researchers.

The word methane comes from the Greek “Μεθάνιον αέριον” (*Methanion Aerion-swamp or foul air/gas*) and thus shows that the Greeks already centuries ago knew about the flammable gas. In Asia Minor, in places where ignited natural gas (methane) sources have been well known, is a volcanic area in which such gases occurred and this gas was named *Methana*. The alchemists in the Middle Ages knew methane as a swamp gas under the name *marsh gas*.

One of the earliest scientific “methane” gas discoverers was the Belgian Jan Baptista van Helmont (1579–1644) in 1630; his knowledge is documented in a communication about an inflammable gas “*gas pingue*” emanating from decaying organic matter. In 1667, the British Thomas Shirley (1638–1678) described “coal bed methane gas” more precisely in a brief report entitled “*A Well and Earth in Lancashire taking Fire at a Candle*” in the “Transactions of the Royal Society,” about his observations in February 1659. The Italian Alessandro Giuseppe Antonio Anastasio Volta (1745–1827) wrote a letter on November 14, 1776, about a combustible gas “*Aria inflammabile nativa delle Paludi*” evolved when the bottom sediments of ponds near the town of Como, northern Italy, and in the Lake Maggiore, were stirred. He experienced that the gas exploded when mixed with air and ignited; he even determined the gas-to-air ratio that resulted in the loudest explosion. It was in 1804 when the British

John Dalton (1766–1844) established the chemical constitution of methane. The gas attracted the attention of famous scientists of those days. The British William Henry (1775–1836) deduced the probable identity of the synthetic illuminating gas as methane. In 1806, he showed that Volta’s gas was identical with methane gas.

The first allusion to animal manure came from the British Sir Humphrey Davy (1778–1829), who reported the presence of combustible biogas in fermenting farmyard manure, in 1808. Therefore, he can be considered as the first real discoverer of biogas as a mixture of methane and carbon dioxide.

By that time the physical scientists (physicists and chemists) had advanced knowledge about biogas as far as their knowledge allowed, and from thereon the microbiologists took over the scientific investigation on biogas. In 1868, the French microbiologist Mme. Antoine Bechamp (1816–1908) identified the micro-organism responsible for methane production. She showed as well that different fermentation products are formed during the digestion process, depending on the type of substrate. The Russian Leo Popoff from Petersburg published 1875 in Strasbourg, Elsass, that fermentation of cellulose could form *swamp gas* at temperatures still as low as 6°C. His experimental studies brought out the optimum temperature for their action and the effect of antiseptics, with some knowledge of the gaseous decomposition products.

The first attempts in using biogas in France were undertaken when the French Ulysses Gayon (1845–1929) produced biogas energy from animal manure. In 1875, he became director of an agricultural research institute in Bordeaux. His trials to produce biogas from manure and to use this gas for lighting and heating were published in the *Comptes Rendus of the Séances de l’Académie des Sciences*, tome 90, 1884. Dr. P. Duvernay reported about this event on March 5, 1884, in the daily newspaper “Le Figaro” under the title “*Une Drôle d’Eclairage*.”

Already earlier, in 1881, the French journal *Cosmos* cited the first full-scale anaerobic treatment of domestic wastewater as “*Mouras Automatic Scavenger*.” Louis Mouras of Vesoul, France, obtained

a septic tank patent in 1881 and was credited with this invention. Baffles, which regulate the flow and increase sanitization, were added in 1905 in order to make the septic tank more efficient. It is reported that this kind of septic tank without biogas recovery was introduced in the USA in 1883, in England in 1895, and in South Africa in 1898. Anaerobic digestion is therefore the oldest technology applied for domestic wastewater treatment. Since 1850 until this date, open constructed rectangular settling tanks (cesspools) were operated intermittently, meaning that the sewage inflow had to be stopped regularly for sludge removal.

In 1895, Donald Cameron, City Surveyor of Exeter, England, constructed in this town a line of six “*Mouras*” septic tank, covered to avoid smell, as the tanks were placed near dwellings. From 1911 onward, under the guidance of Mr. T. Moulding, the collected biogas was used in sewer gas destructor lamps, a type of street gas lighting.

Combustible biogas that could be obtained from human excreta was also demonstrated in India, where in 1897 a biogas-generating plant treating toilet wastewater was constructed in Matunga, more specifically in the Homeless Lepers’ Asylum, known as the Acworth Leprosy Hospital in Wadals, founded 1890. The biogas was used for lighting. This may be the first application worldwide of the so-called biogas-sanitation.

The roots of technical applicability of microbiological digestion probably lie with methane-producing bacteria “*Methanobacillus omelianskii*” discovered by the Ukrainian Vasilii L. Omelianskii (1867–1928). From 1893 to 1928, he worked in the department of general microbiology of the Institute of Experimental Medicine. His classic studies on methane fermentation bacteria were reported during 1903/1904. He isolated organisms that produced hydrogen, and acetic and butyric acids. He also reported the formation of methane from hydrogen and carbon dioxide. The development of microbiology as a science led to more research by the American team A.M. Bushwell, G.E. Symons, C.S. Borrruf, and W.C. Boyle; they published in 1936 a scientific formula describing the composition of biogas based on the chemical composition of the substrates undergoing an anaerobic digestion process.

William Owen Travis sought to improve the contact bed procedure for municipal wastewater treatment. As local health officer in charge of a contact filter at Hampton, England, Dr. Travis was quite familiar with the problem of bed clogging. His solution, introduced in 1904 as the *Travis Hydrolytic Tank*, was essentially configured as a multistage septic tank. Successively divided into detritus, hydrolytic, and finishing tanks, the latter two zones contained wooden baffles or laths placed in a parallel array. These baffles were intended to retain fine particles for subsequent degradation. Based on this development, Karl Imhoff (1876–1965) shifted the focus from anaerobic wastewater treatment to anaerobic sludge treatment with his *Imhoff tank* (1905/1906). An upper section of this tank is designed for sedimentation; the solids fall from it through a slot into a lower section for digestion. Experiments on a similar unit, called Biolytic tank, were carried out in the USA between 1909 and 1912. With the installation of the first sludge heating system, separate digestion of sludge was reported at the Essen-Rellinghausen wastewater treatment plant in Germany in 1927. The separated sludge digestion became increasingly popular in larger German towns and cities, and the importance of methane gas generation was widely recognized. Methane gas was used for digester heating; it was collected and delivered to municipal gas systems, and it was used for power generation for operating biological wastewater treatment systems, and as transport fuel. The sale of sewage gas was, in addition to the sale of sewage sludge as fertilizer, one of the few ways from which the sewage treatment plant could generate revenue to reduce wastewater treatment costs. In the USA at Belleville Water Works, Maryland, Illinois, the first *Clarigester* was installed in 1938 to separate the sludge from the wastewater stream, and to treat the sludge anaerobically, recovering sewage biogas.

In China in 1927, Luo Guorui developed in Shantou city, Guangdong province a small-scale agricultural biogas plant, using the gas for lighting; the design was based on existing urban household septic tanks. This may be considered as the worldwide first agricultural biogas digester.

Inspired by the research work of the Rothamsted agricultural experimental station in England in

1929, the British Lord Iveagh was the first builder of a European agricultural biogas reactor on his property in Pyrford Court, Surrey. He had a 300 m³ volume biogas tank and used straw as feedstock, which was inoculated twice a year with fresh manure. For 20 years, the daily gas production was recorded, which indicated daily 12–120 m³. The gas was used on the farm even for cooking and lighting. It was used until 1960, before it ceased operations.

G. Ducellier and M. Isman developed the design and prototypes of another dry-fermentation biogas digester since 1937 at the Institute of Agriculture in Algeria. Since 1946, the technology had been transmitted to France and Mr. Renandat was one of the first farmers at Levroux, Indre, who constructed a biogas plant which consisted of a battery of four tanks (100 m³ volume), gasholder and compressor, pressure storage tank, and a biogas-fueled tractor. It was estimated that such an installation would pay for itself within ten years of construction by the production of gas and savings in fertilizer costs. Since then, French farmers constructed perhaps 1,000 low-tech plants along the lines of the *Ducellier-Isman* design.

In India, in 1946, a social worker within the Khadi and Village Industry Commission (KVIC), Mr Jashbhai Patel, started to work on developing a liquid manure biogas digester design placing the digestion chamber below ground.

Imhoff drafted in 1944 an agricultural biogas plant for the farm Zitzstaudenhof in Olching, Germany. Although this plant was never built, the draft, published several times by the designer, gave the model for the first agricultural biogas plant called “*Darmstaedter Gaerkanal - gas factory on a farm*” in 1947/1949 on the farm Bertaloth in Rohrbach; improvements were guided by Prof. F. Reinhold, State Laboratory of Road and Urban Engineering at the Technical University Darmstadt, and built by the Casting and Valve Works Kaiserslautern, Germany.

Nowadays, such low-tech anaerobic reactors are widely adopted for the stabilization of municipal sludge, human excreta, and animal manure, aiming at the generation of renewable energy in the form of methane and the generation of bioslurry.

The National Institute for Water Research of the South African Council for Scientific and Industrial Research published in 1950 research results from G.J. Stander, which recognized the importance of solid retention time (SRT) for a successful anaerobic treatment of different wastewaters. This has been the basis for the worldwide development of the so-called high-rate anaerobic biogas reactors, in which SRT and hydraulic retention time (HRT) are uncoupled, but both fractions are undergoing anaerobic treatments in one constructed tank. Further development led to a wider application of anaerobic biotechnology, particularly for industrial wastewater treatment combined with biogas recovery. Some of the present widely used high-rate anaerobic treatment processes for industrial wastewater treatment are anaerobic filter (AF), up-flow anaerobic sludge blanket (UASB) reactor, expanded granular sludge bed (EGSB), fluidized bed, internal circulation (IC) reactor, and hybrid systems.

Basics of the Biogas Process

Anaerobic digestion is a complex biological process that takes place in the absence of oxygen. The decomposition process is possible under anoxic (presence of nitrate) and anaerobic conditions: Bacteria split organic substances into their components, and these components are “re-arranged”; other bacteria originate from biochemical degradation.

The digestion is a multistage process consisting of hydrolysis, acido- and acetogenesis, and methanation performed by different bacteria and microorganisms. In low-tech biogas systems, the different degrading reactions take place in one or two digester(s) or digestion chambers. The digestion process starts with hydrolysis of the input material caused by exoenzymes of facultative and obligatorily anaerobic bacteria in order to break down insoluble organic polymers such as cellulose, proteins, and fats. Acidogenic bacteria then convert sugars and amino acids into carbon dioxide, hydrogen, ammonia, and organic acids, followed by acetogenic bacteria converting the resulting organic acids into acetic acid, along with additional ammonia, hydrogen, and carbon dioxide. At the end of the process, methanogens convert these products into methane and carbon dioxide.

To summarize, the anaerobic digestion process consists of the following steps:

1. Hydrolysis: (a) The organic matter is hydrolyzed by extracellular enzymes. (b) Bacteria decompose the long chains of complex to simpler substances, for example, polysaccharides to monosaccharides.
2. Acidification: (a) Acid-producing bacteria convert intermediate fermentation products into acetic acid, H_2 , and CO_2 . (b) Acid-producing bacteria create anaerobic conditions for CH_4 (methane)-producing bacteria.
3. Methanization: Methanogens, that is, methane-producing bacteria, acetic acid, and/or hydrogen are used to form methane. Sulfate reduction leads to the formation of hydrogen sulfide.

Higher concentrations of, for example, ammonia, heavy metals, light metal cations, oxygen, short chain organic acids, other organic acids, and sulfides could inhibit the anaerobic process. Short-term biogas productivity tests are available to investigate this.

One result of such an anaerobic digestion is biogas. The term “biogas” refers to a gas produced by anaerobic digestion or fermentation of organic matter including manure, sewage sludge, municipal solid waste, biodegradable waste, or any other biodegradable feedstock under anaerobic conditions. Biogas is comprised primarily of methane and carbon dioxide. In conventional septic tanks, biogas from Imhoff tanks (combined settler and sludge treatment units) and anaerobic lagoons vented out, creating climate critical emissions due to its methane content. The rate of methane production depends on the rate of removed COD, BOD, and the temperature. It is also common to relate the biogas production to the dry matter (DM) or organic dry matter (ODM) of the input material.

Practically most anaerobic bioprocesses stabilize organic wastes that are formed from mixtures of fats, proteins, and simple carbohydrates, and this typically results in biogas composition illustrated below:

- Methane (CH_4): 50–70 vol%
- Carbon dioxide (CO_2): 28–48 vol%
- Other gases: up to 2 vol% including trace components such as hydrogen, nitrogen, oxygen, ammonia, argon, carbon monoxide, hydrogen sulfide, non-methane volatile organic carbons, halocarbons

Biogas-producing systems are used as environmentally friendly technology for waste and wastewater treatment, and for renewable energy generation in many countries. The average calorific value of biogas is about 6 kWh/m^3 ; this corresponds to about half a liter of diesel oil. The net calorific value depends on the efficiency of the burners or appliances. Methane is the valuable component under the aspect of using biogas as a fuel.

Biogas can be used for (in order of simplicity, with simplest option first): cooking with gas stoves, lighting, heating, electricity generation, simultaneous generation of both electricity and useful heat (with combined heat and power (CHP) units), cooling, or as transport fuel. Some options are only feasible for larger biogas systems, but the smallest combustion engine-based “mini” biogas GENSETs – commercially offered – is 4 kVA.

As common figures for methane production $0.25 \text{ m}^3 CH_4/\text{kg COD}$ (chemical oxygen demand) removed or 1 kg BOD (biological oxygen demand) removed results in practice in about 0.6 kg methane at 273 K (energy content of methane 35.8 MJ/m^3).

Sulfur content in biogas in form of hydrogen sulfide (H_2S) has to be taken into account and possibly filtered out or eliminated chemically. H_2S is a colorless gas presenting a strong odor of rotten eggs; it fatigues the sense of smell, which cannot be counted on to warn of the continued presence of the gas. While biogas is used for cooking, the presence of H_2S in the biogas results in smell disturbance and faster corrosion of the cast iron burner parts, which are in direct contact with biogas.

Additionally, a part of H_2S might be converted through the incomplete combustion of biogas into sulfur dioxide (SO_2), which could result in headache and breathing problems. Even it is known that H_2S needs a lower (260°C) combustion temperature than methane (CH_4) at 560°C , temperatures over 850°C throughout the flame are necessary to prevent the formation of carbon monoxide (CO), partially oxidized hydrocarbons, dioxins and furans, and polycyclic aromatic hydrocarbons (PAHs).

Stoichiometrically, 9.6 volumes of air per volume of methane are required to achieve complete oxidation by burning. For the typical biogas composition given above, this ratio reduces to 5.7:1. Similarly, the energy released by pure methane is 36 MJ/m^3 (gross calorific value) and is reduced to 21 MJ/m^3 for biogas.

Organic material degrades more rapidly at higher temperatures because all biological processes operate faster at higher temperatures up to the limit of sterilization. The three ranges of temperatures in which methanogens could work are called psychrophile (8–25°C, with an optimum at 17°C), mesophile (30–42°C, with an optimum at 40°C), and thermophile (53–65°C, with an optimum at 55°C).

Low-tech, non-heated, and poorly insulated biogas systems are often applied in countries where the ambient average annual temperature ranges above 12–25°C. In ambient temperatures below 8°C, digestion capability is very much reduced without active and passive heating and insulation of the digester. The methane formation process is also sensitive to daily temperature variations of more than 3°C; therefore, day-night variations or temperature shock loads have to be kept in a limited range to ensure a steady biogas production. The higher the process temperature the more sensitive is the process (bacteria).

To improve low-tech biogas systems, the application of improved insulation (above and below ground), keeping the plant environment dry (drainage layer and plant area roofing), active and/or passive heating of plant, and filling substrate should be considered (preheating, solar heating), depending on available design, funds, and micro-environment.

Biogas Systems and Their Importance

Biogas systems are defined here as “engineered systems designed and constructed to utilize biological processes which break down solids and soluble organics in the liquid by anaerobic bacteria action under exclusion of free oxygen in treating organically loaded sludge.”

A process design differentiation between highly diluted (low dry matter content) wastewater and solids or sludge (high dry matter content) treatment has to be made. For the first one, bacteria have to be accumulated and kept in the system, while in the second one, organic biodegradable solids are hydrolyzed and then converted into biogas. Anaerobic wastewater treatment, biogas sanitation, bio-waste fermentation, and manure treatment are using the same biological process, but the goal of anaerobic wastewater treatment is to purify wastewater. The goal of animal manure treatment in biogas plants is to generate energy, avoid

methane emissions, and to produce an improved soil conditioner. The goal of biogas sanitation is to prepare “humanure” for safe reuse and to produce biogas. The goal of bio-waste fermentation is to reduce volume of waste for post-treatment and to produce carbon emission free energy, rather than to prepare manure for fertilizing reuse and to produce biogas.

Biogas systems may treat a wide range of waste and wastewater; here a focus is put on biogas production in developing countries (low-tech applications) for small-scale heat and cooking gas provision, by treating animal manure, organic waste from industries and settlements, black water or brown water, excreta, fecal sludge, wastewater from low or no flush toilets, and kitchen waste.

Anaerobic treatment units are often an alternative or a pre-treatment to aerobic treatment systems due to their energy and soil conditioner production capacity, low-tech components, and adaptability. It is also a technology for organic sludge treatment. The main advantages of the anaerobic treatment process compared to the aerobic treatment process are the generation of biogas and significantly less excess sludge production as well as smaller reactors. The fact that the plant nutrients phosphorus and potassium are not removed in the treatment process can also be an advantage for the application of the effluent in agriculture to replace mineral fertilizer. However, the effluent should never be discharged directly into water bodies without further treatment, unless the carrying capacity of the receiving water body is not exceeded. Anaerobic technology has advantages in terms of nutrient recycling, energy balance, and CO₂ emission reduction compared to conventional aerobic treatment systems.

Toilet wastewater alone could not produce enough biogas to cover completely the energy demand for cooking or lighting of a household, at least the excreta of five persons are needed to cover the daily cooking energy demand of one person. Feeding easy biodegradable organic kitchen waste or animal dung into the biogas-sanitation digester could increase the biogas yield. An organic garbage disposal unit in the kitchen sink (grinder) is useful in this respect.

In decentralized or semi-centralized wastewater treatment systems, biogas-sanitation units are often designed as primary treatment of wastewater to remove large particles and some organic matter by settling and digestion.

Besides the feedstock material, local circumstances must be taken into consideration before designing a biogas plant, such as the dilution of the influent with (gray) water or urine; addition of organic waste; the settle-able solids content in the influent; the climate and soil temperatures; available space; and the intended reuse or disposal pathway.

Methane (CH_4) is a greenhouse gas that remains in the atmosphere for approximately 9–15 years. Methane is 21 times more effective in trapping heat in the atmosphere than carbon dioxide (CO_2) over a 100-year period. It is emitted from a variety of natural and human-influenced sources. Human-influenced sources include landfills, natural gas and petroleum systems, and agricultural activities; coal mining; stationary and mobile combustion; wastewater treatment; and some industrial processes. Methane is also a primary constituent of natural gas and an important energy source. As a result, efforts to prevent methane emissions or utilize methane can provide significant energetic, economic, and environmental benefits.

Biogas systems can be classified according to various parameters; the three most important design criteria are (1) hydraulic retention time (HRT in days), (2) organic load rate (OLR in kg COD/m^3 or kg ODM/m^3 active fermenter volume), and (3) settled sludge retention time (SRT in days or years).

The required hydraulic retention time (HRT) of the substrate in the digester depends on the process temperature and the type and concentration of the substrate itself. This will then determine the volume of the digester. Digesters are generally designed for an optimum economic balance between highest biogas yield and smallest volume (HRT). Therefore, the retention time is chosen as the total time required, producing a certain amount of the total biogas (to size the digester to obtain all possibly generated biogas is often not economically viable). A low-tech energy-optimized biogas system should have a minimum of 20 days of hydraulic retention time due to bacterial reproduction time, but from a health point of view, the hydraulic retention time in a biogas-sanitation system should be extended to more than 60 days, if no adequate post-treatment of effluent is foreseen.

For animal manure undergoing low-tech fermentation process in the upper psychrophilic and lower mesophilic temperature range ($17\text{--}33^\circ\text{C}$), the

following approximate hydraulic retention time values are usually applied:

- Cow or cattle manure: at least 30 days
- Pig manure: at least 25 days
- Poultry manure: at least 40 days
- Animal manure mixed with easy biodegradable plant material: about 80 days
- Fecal material: at least 60 days

A sludge retention time (SRT) of at least 10 days is necessary to promote methanogenesis in the anaerobic treatment of primary sludge at a process temperature of 25°C while a sludge retention time of 15 days is necessary for sufficient hydrolysis and acidification of lipids. For temperatures as low as 15°C , a sludge retention time of at least 75 days has to be considered to achieve methanogenic conditions. The longer the sludge retention time, the better the degradation and stabilization of the sludge will be and less sludge will remain. This is of special importance for biogas-sanitation units; the handling of not-sufficient treated sludge can be also a problem in densely populated areas.

Parameters for monitoring anaerobic processes are: organic dry matter content, pH value, carbon-to-nitrogen ratio (C/N ratio), redox potential, volatile fatty acids, moisture content of the biogas, temperature stability, and substrate composition. Biogas amount and quality should be used for monitoring the plant performance – related to the applied feedstock biogas potential; the total solids content in the reactor influent and effluent is an important parameter, too.

It is always important to maintain by weight a carbon-to-nitrogen (C/N) ratio between 8 and 30:1 for achieving an optimum rate of digestion. Combining materials low in carbon with those that are high in nitrogen can manipulate the C/N ratio. If the C/N ratio is very high, nitrogen limitation could cause low gas production, since nutrients for the growth of anaerobic bacteria are lacking. If the C/N ratio is very low, the pH value may increase, and will have a toxic effect on bacteria, and also result in lower biogas production.

Different types of biogas digesters could be combined (so-called combined systems, multistep systems, or decentralized wastewater treatment systems) in order to benefit from the specific advantages of the different systems. The quality of the final effluent

from the systems improves with the multiple steps of the treatment facility. Design and engineering information for the worldwide used fixed dome, baffle reactors, anaerobic filter, covered lagoon, stirred systems, up-flow systems, or composite plant design variations are available through many websites, literature, and expert consultations.

Local design adaptations to different local human diets, livestock keeping habits and manure types (influencing organic load and biogas potential), sanitization needs, and effluent reuse options (for energy crops, tree nursery, grassland, vegetable, grains) are always necessary.

Selected Low-Tech Biogas Design and Post-Treatment Units Descriptions

Below some selected low-tech biogas designs are described. The key to the optimal operation of a reactor selection and design is to understand the bacteria: how much, how active, how good in resisting shock loads.

Fixed Dome Digesters. Chinese model biogas plant with manhole (also called drum-less digester) consists of an underground compartment (fermentation chamber) with a dome on the top for gas storage. In this design, the fermentation chamber and gasholder are combined as one unit. The construction details of a biogas plant (with or without baffle(s), size of integrated gasholder) depend on the further treatment step chosen and on the expected biogas use pattern. In a special design, the so-called biogas settler (BS), to achieve that the sludge retention time (SRT) is longer than the hydraulic retention time (HRT), baffle or separation walls should be added when it is operated as stand-alone sanitation system. The accumulated settled sludge must be removed from the base of the biogas settler (BS) periodically.

Floating Drum Digesters. In the digester chamber, a floating drum (bell) is placed on top of the digester to collect the biogas produced from the digester. Thus, there are two separate structures for gas production and collection. The construction details of a biogas plant (with or without baffle) depend on the further treatment step.

Covered Lagoon Digester. A sealed pond or lagoon operated for the stabilization of manures, anaerobically and fitted with an impermeable cover (polyvinyl

chloride (PVC), ethylene propylene diene monomer rubber (EPDM), or high density polyethylene (HDPE)) to capture the biogas generated as the product of waste stabilization. Disadvantages are the land area needed for anaerobic lagoons and sludge sedimentation problems, if digester is un-stirred.

Plug-Flow Biogas Digester. Plug flow is a simple model of the velocity profile of a fluid flowing in a pipe. In plug flow, the velocity of the fluid is assumed to be constant across any cross section of the channel perpendicular to the axis of the channel. Essentially no back mixing is assumed with “plugs” of fluid passing through the reactor. Many different forms of construction are known, for example, fixed-dome tunnel plants, floating gas holder tunnel plant, PVC or PE-plastic bag “sausage” tubular digester, composite tank plant, covered sedimentation channel lagoons. The digester is a long, rectangular container or tank or channel (1/5: about 1 times large related to 5 times long), with gastight cover. New material added to the tank at one end pushes older material to the opposite end.

Anaerobic Baffled Reactor. The anaerobic baffled reactor (ABR) has a series of up-flow and down-flow baffles which are used to direct the flow of wastewater in an up-flow mode through a series of sludge blanket reactors. This configuration provides a more intimate contact between anaerobic biomass and liquid, thus improving the treatment’s performance. It could be used as primary treatment as well, especially where influents are highly diluted with flush water (from pig stable or toilet buildings). Separation of the sludge retention time (SRT) from the hydraulic retention time (HRT) is the key to the successful operation of an anaerobic baffled reactor. Due to this fact, a baffled reactor is considered as the best alternative to aerobic treatment and posterior to primary settlement in a biogas digester. The treatment efficiency achievable is usually superior to that of a conventional septic tank.

Anaerobic Filter. The anaerobic filter (AF) is suitable for effluents with a low content of suspended solids and a narrow COD/BOD ratio, for instance, from biogas settlers or biogas septic tanks or anaerobic baffled reactor as initial treatment unit. The bacteria in the filter are immobile and generally fix themselves to solid particles (carrier material) or to the reactor walls. Filter materials like rocks, cinder, plastic, or gravel provide additional surface area for bacteria to settle. The larger

surface area for the bacterial growth helps in the quick digestion of the wastes. A good filter material provides a surface area of 90–300 m²/m³ reactor volume. Anaerobic filters are reactors consisting of supporting material layer. On the surface of these material layers or bed fixation of microorganism the development of biofilm takes place. In the case of concentrated feedstock, the risk of blockage of the filter material increases with the concentration of suspended solids. Therefore, it is best suited for posttreatment.

Up-flow Anaerobic Sludge Blanket Reactor. The up-flow anaerobic sludge blanket reactor (UASB) is a tank filled with anaerobic granular or flocculants sludge with good settling properties. (The bacteria spontaneously agglomerate to form granules.) Influent wastewater is distributed at the bottom of the UASB reactor and travels in an up-flow mode through the sludge blanket. The anaerobic degradation of organic substrates occurs in this sludge blanket, where biogas is produced and serves to mix the contents of the reactor as they rise to the surface. The UASB reactor has the potential to produce higher quality effluent than biogas septic tanks, and can do so in a smaller reactor volume. The design of an UASB reactor must provide an adequate sludge zone since most of the biomass is retained there. The granulated sludge zone is completely mixed because the wastewater is fed into the reactor through a number of regularly spaced inlet ports. The UASB is also characterized by a much longer SRT in comparison with the HRT.

Development of Biogas Use in Various Countries

In the following some developing country programs and developments in the biogas sector are briefly described; the list is however incomplete as about all countries have nowadays their own biogas history.

Asia

Bangladesh The Institute for Fuel Research and Development (IFRD) of Bangladesh Council of Scientific and Industrial Research (BCSIR) has been the main actor for the dissemination of domestic biogas plants in Bangladesh till date. Other organizations being involved at different stages have been Bangladesh Rural Advancement Committee (BRAC), Local Government Engineering Department (LGED),

Department of Environment (DoE), Grameen Shakti (GS), Bangladesh Agricultural University (BAU), Bangladesh Small & Cottage Industries Corporation (BSCIC), Danish International Development Agency (DANIDA), and Department of Livestock Services (DLS).

In 1972, BAU set up a first floating-drum plant in the University campus to study the characteristics of gas production, followed later by a plant that provided gas for cooking and lighting for a family of six members. In the campus of BCSIR, another plant was constructed by IFRD in 1976, followed by a plant at the KBM College in Dinajpur in 1980. Seventy-two plants were constructed for farmers with technical assistance by IFRD. In 1981, DoE started its program through which about 150 floating-drum and 110 fixed-dome plants were installed by contractors free of cost. Other efforts were undertaken by BSCIC (a number of plants), DANIDA and LGED (more than 200 trench and bag type digester), and DLS (about 70 plants). Also the Grameen Bank installed 17 polyethylene plastic bag digesters. Under the “Fuel Saving Project” implemented from 1989 to 1991, IFRD trained local youths who constructed in total 146 plants in the premises of well-to-do farmers. The gasholder was supplied free of cost. In 1994, LGED supported the establishment of an ecological village (Amgram in Madaripur district) among others by converting 95 open latrines into family biogas-sanitation plants.

An important dissemination push was delivered by the “Biogas Pilot Plant (1st phase) Project” implemented by BCSIR in the period July 1995 to June 2000. In total, 4,664 fixed-dome plants were constructed throughout the country. BCSIR employed and trained 128 diploma civil engineers who were assigned responsibilities for motivation, installation, and after-sales service throughout the country. In addition, 898 youths were trained to support the project. The biogas farmers received an investment subsidy of Taka 5,000 (US\$ 64) under the project. Memorandum of Understanding (MoU) were signed between BCSIR and several other institutes like BRAC, LGED, and DLS for research, training, and dissemination of the biogas technology. The cooperation with BRAC was the most successful as this organization managed to motivate about 1,200 farmers. An interim evaluation report in 1999 reported 99% of the plants installed under the

project were in operation, while 91% of the owners could meet their household fuel demand through biogas. Bioslurry from the biogas plants was used in horticulture, pisciculture, and agriculture. The average saving per plant amounted to Taka (US\$ 10) per month.

As the first phase was successfully completed and the potential for biogas in Bangladesh considered huge, BCSIR implemented the second phase of the Biogas Pilot Plant in the period July 2000 to June 2004. The target for this phase was to put on 20,000 biogas plants, out of which 17,194 plants were finally realized. The investment subsidy for the owner was increased to Taka (US\$ 96) per plant. In addition to the diploma civil engineers employed and paid on a monthly basis by BCSIR, an agency system was introduced on incentive basis. About 50 agencies were recognized in defined areas (mostly districts) and received a lump-sum fee of Taka (US\$ 64) per plant as service charge. About 1,000 masons and youths were trained under the project as well.

In the period from October 1998 to June 2003, the LGED implemented a parallel biogas project aiming to install 1,900 domestic plants. As the investment subsidy for this project amounted to Taka (US\$ 64) only, it proved to be rather difficult to motivate farmers during the implementation of the second phase of the Biogas Pilot Plant Project when BCSIR was providing a subsidy of Taka 7,500 to farmers. Therefore, the LGED project was terminated prematurely, after having constructed about 1,120 biogas plants. Under the Secondary Town Infrastructure Development Project-II, another 20 domestic biogas plants were installed using human excreta only.

Of more recent date is the initiative of GS aiming to construct not less than 200,000 biogas plants within a period of five years. This initiative is still in the preparatory phase; at the time of the mission a total of 10 plants were installed or under construction. Agency holders also continued to construct plants without any subsidy in very limited numbers after the termination of the second phase of the BCSIR pilot project in June 2004. By the end of 2008, about 40,000 family-sized low-tech biogas plants of different designs had been installed throughout Bangladesh.

Since 2006, Netherlands Development Organisation (SNV) is implementing the “National Domestic

Biogas and Manure Programme” (NDBMP) in Bangladesh involving the “Infrastructure Development Company” (IDCOL), and other national and local partner organizations. The overall objective of the NDBMP is to further develop and disseminate domestic biogas plants in rural areas with the ultimate goal to establish a sustainable and commercial biogas sector in Bangladesh. This program will help to attain Millennium Development Goals (MDG) set by Government of Bangladesh as well. The overall objective of the National Domestic Biogas and Manure Programme (NDBMP) is to develop and disseminate domestic biogas plants in rural areas with the ultimate goal to establish a sustainable and commercial biogas sector in Bangladesh. The National Strategy for Economic Growth, Poverty Reduction and Social Development prepared by the Ministry of Finance and Planning also puts emphasis on “creating a policy environment that is capable of providing right incentives to adopt new technologies.” It also emphasizes the integration of environmental conservation strategy into national poverty alleviation strategies. NDBMP further contributes to achieve millennium development goals set by the Government. Contribution of biogas in this regard will help poverty reduction through (1) savings on energy expenditure, (2) increased agriculture production by maximum utilization of bioslurry as fertilizer, (3) gender equality through empowering women in decision making and maximization of their participation in the program, (4) improved health through provision of clean cooking energy, (5) improving sanitation by toilet construction connection to the biogas digester, and (6) creation of opportunities for local employment.

Until April 2009, about 35,000 plants were already newly installed in Bangladesh. Considering only smaller sized household biogas plants the total technical potential from the available raw material reaches up to about a potential of three million biogas plants. Under the on-going program a total of 37,269 plants are aimed to be constructed in the period 2006–2012. Several activities are implemented to achieve this target: promotion and subsidy administration to provide Taka 9,000 (US\$ 115) per household as investment subsidy. To ensure proper functioning of the plant, guarantee on plants for 5 years and maintenance services are provided for 3 years, and training on

operation and maintenance will be provided to each biogas plant owner family. Trainings will be developed and imparted to the staff of the partner organizations to strengthen their capabilities. Proper management and utilization of bioslurry is given high emphasis. IDCOL plays a role of refinancing whereas another program implementing organization will be engaged for program activities of the (technical) implementation. This program is subsidized by the Government of Bangladesh, the Netherland development cooperation, local Micro Finance Institutions, and supported with development cooperation loans by the German Bank for Reconstruction and Development (KfW). In addition to these budgetary sources, there is an opportunity of generating carbon finance through trading carbon emission reduction from well-performing biogas plants.

China In 1927, Luo Guorui developed in Shantou city, Guangdong province, a small-scale agricultural biogas plant, based on existing urban household septic tanks. As a standard, the toilet and the pigsty were connected to an underground 8 m³ digester. The *Shantou Guorui Natural Methane Gas Lamp Company* has commercially promoted the system. In the *Shantou* newspaper in 1930, he advertised the benefits of natural methane lamps. The inventor moved in 1931 to Shanghai and founded the *Chinese Guorui General Natural Methane Company* with many branches along the Yangtze River and in the southern provinces. In April 1935, Chinese lecture notes about *Guorui methane digesters* were published as the first scientific presentation about low-tech household-based agricultural biogas technology in the world; this publication initiated the first wave of biogas application in China.

Since 1957 biogas research and technology were developed at high speed, and the Chinese government promoted farm biogas technology vigorously. At the Beijing Agricultural University, 1958, the first “international” training course on low-tech biogas technology was held with Soviet Union invitees. The technology was found to be appropriate to both the livelihood systems of rural farmers and the political intention of the communist party to become independent of fertilizer imports. Up to seven million biogas units have been constructed in China between the years 1968 and 1978. The main feedstock was pig manure,

and the main emphasis of the Chinese program was to provide an efficient and economic fertilizer, rather than household energy aspects of biogas technology. One of the lessons learned from this Chinese biogas program is that technology dissemination to a very large number of households is possible if it is supported by a strong political will.

The today worldwide known Chinese round shaped fixed-dome biogas plant was developed in 1973, and in 1980 – after 7 years of experience and adaptations – it was standardized nationwide. In 1980, the China Biogas Association was founded to coordinate the biogas development inside the country and internationally.

In 1978, the Zhangzhou College of Education developed a small-scale three-chamber biogas-sanitation digester for anaerobic treatment of excreta from household toilets, which was added to the agricultural standards. In 2000, the composite fiberglass household biogas plants entered the commercial market with volumes between 6 and 10 m³. This prefabricated biogas digester offers some significant improvements: improved gas tightness, long life span, lower maintenance costs, and shorter construction period from at least 10 days with brickwork and concrete to half a day. Since then, other prefabricated models, mainly based on high-density polyethylene (HDPE) material, have been developed and entered the market as well.

In 2003, the national biogas development plan for China 2003 till 2010 suggested to increase the use of biogas until the year 2005 from 11 million households to 20 million households, promoting biogas use in one of ten agricultural households. In 2010, the number of biogas-using households reached 40 million, with an operational rate of at least 60%, as estimated by Chinese evaluations. Since 2003, the government subsidizes each low-tech biogas plant with an average of 1,000 CNY (about 110 €).

India In 1946, a social worker within the Khadi and Village Industry Commission (KVIC), Mr Jashbhai Patel, started to work on developing a biogas design placing the digestion chamber below ground. Whereas in the former Indian model, reactor and gasholder have been separated, the new feature integrated gasholder and reactor into one unit, saving both space and material. Further innovations of this design were the

continuous flow system and automatic overflow when overloading. It was also equipped with a device that should prevent scum to enter the gas pipes. The first unit of this type was installed in 1950 at Osmania University, Hyderabad. The design was called Gramalakshmi; Grama meaning “rural” in Hindi, and Lakshmi is the Goddess of wealth and prosperity in the Hindu religion. There is also a notion of the word Grama toward the Gandhian movement of rural development.

The work of Mr. Patel continued during the 1950s; other institutions such as the Rama Krishna Mission in Calcutta and Khadi Pratisthan Sodepur in West Bengal did also develop new designs. A number of pilot units were constructed especially in the regions of Maharashtra and in the vicinity of Delhi. KVIC included dissemination of biogas technology in its rural development program since 1961, as a result of the earlier field trials. The Planning Research and Action Division (PRAD) of Uttar Pradesh took further national initiatives by establishing a research station in Ajitmal. This research station later became known as the Gobar Gas Research Station, and one of the influential persons was Mr. Ram Bux Singh. Until 1974, about 6,000 biogas units were set up in India.

In 1975, the years following the worldwide energy crisis, it was considered that a well-tested low-tech biogas technology existed, and the required infrastructure for carrying out a nationwide dissemination program was planned, with the aim to install 1.5 million biogas units by 2001. Many organizations and institutions were involved, but the main responsibility for the implementation of the program was held by KVIC. The biogas program was in many respects in line with the development goals defined by Indira Gandhi and the government. The technology was indigenously Indian; it was expected to develop the rural areas and to improve the livelihoods of rural population. It was also a response to the increased oil import expenditures India had experienced some years ago. Identifying the fuel wood crisis, biogas technology was considered, among many planners and policy makers, to be a real solution to the problem. International organizations and donors were beginning to show interest in the technology. Rural development and appropriate technology were attractive for any development program. Small-scale technologies were given attention as

possible solutions to the limits of finite resources. It was considered that the dissemination of biogas technology was a potential way to improving the situation for rural people with limited budgets. In 1978, the Gobar Gas Research Station in Ajitmal, Uttar Pradesh, came up with a prototype of a new design called Janata biogas plant, meaning “public” or “people” in Hindi. The Janata design was similar in several ways to the Chinese fixed-dome design, but with one notable difference: The Janata design was not equipped with a manhole on the top of the digester, which was a common feature of Chinese designs. The (Chinese) manhole or the floating gas drum on the top made it possible to use other feedstock than manure, as feedstock that floated on top of the slurry could be taken out. Floating biomass can cause blockage of gas pipes as well as the digester volume is not used efficiently with reduced gas production as a result. Therefore, the main advantage of the Janata type over the KVIC design was the reduced cost for construction. By 1980, approximately 90,000 low-tech rural biogas units had been installed in India of which only a small number were of the Janata type.

The Government of India launched in the years 1981/1982 an extension and development program called National Programme for Biogas Development (NPBD). The Ministry of Agriculture was only to implement the program. NPBD still exists and the goal, as it is presented today, is: *...providing clean and cheap source of energy in rural areas, producing enriched organic manure for supplementing the use of chemical fertilizers, improving sanitation and hygiene and removing drudgery of women* (MNES 1996).

In 1984, the NGO Action for Food Production (AFPRO) introduced their new biogas design called *Deenbandhu* biogas plant meaning “friend of the poor” in Hindi. This design was approved for inclusion in the NPBD in July 1986. The *Deenbandhu* design was claimed to further cut the cost of biogas installations. Actually it was not a really new design, but rather a further development of the Janata type. The cost reduction was due to the use of some standardized pipes and a different construction technique. The design soon became the most popular design within the NPBD.

In 1996, there were a total of seven biogas plant designs approved by the Ministry of Non-conventional

Energy Sources (MNES). Besides the Khadi and Village Industries Commission (KVIC), Janata, and Deenbandhu, there were the Pragrati design, KVIC design with reinforced plastic dome (composite), KVIC design with ferro-cement dome, and the FLEXI-design (rubber based).

Since 2002, national dissemination speed achieved about 1.2 million biogas plants per year, rising from 100,000 units yearly before. Today basically one design, the Deenbandhu, is disseminated throughout the whole country, thus following a “one design fits all” approach.

Nepal Biogas in Nepal can look back on a long, eventful history. The Belgian Reverend Saubolle first introduced it on an experimental basis in 1955. Subsequently, several organizations became involved in promoting the technology. His Majesty's Government of Nepal launched the first official biogas program in 1974. Under this program, the Agricultural Development Bank of Nepal offered construction loans to potential customers. In 1977, the Government established the Biogas and Agricultural Equipment Pvt. Ltd. popularly known as Gobar Gas Company (GGC). This state-owned entity was in charge of the development and promotion of large-scale dissemination of biogas technology in Nepal.

Started in the 1980s as a technological research project with a limited number of test models, it was expanded during the 1990s by the Biogas Support Program into a successful market development program with the active involvement of the private sector and business community. Over the last 20 years, more than 200,000 biogas installations have been built and the sector now comprises more than 70 local companies and employs about 11,000 people.

Pakistan The history of biogas technology in Pakistan started 1974. Around 6,000 mainly small 6 m³ scale digesters have been installed across the country till the end of 2006 – against the technical potential of about five million digesters based on its suitable climate and availability of cattle dung as feedstock.

The Government of Pakistan started a comprehensive biogas scheme in 1974, and commissioned 4,137 household biogas units by 1987 throughout the country. These were metal floating-drum biogas plants with

a capacity varying from 5 to 15 m³ biogas productions per day. This program was implemented in three phases. During the first phase, 100 demonstration units were installed under grant by the government. During the second phase, the cost of biogas plants was shared between the beneficiaries and the government. In the third phase, the government withdrew financial support for the biogas plants, although technical support continued to be provided free of cost. Unfortunately, after the withdrawal of the government financial support, the project did not progress any further.

The Pakistan Centre for Renewable Energy Technologies (PCRET) started the fourth biogas phase in early 1997 with the installation of 4,000 household plants in several major cities of the country, having a digester volume between 5 and 15 m³ biogas productions per day. PCRET disseminated small-scale biogas technology and has supported installation of around 1,600 biogas plants in 2006. In addition, PCRET had plans to install 2,500 plants by 2008 for which the Government of Pakistan had approved financial support. Three community size biogas plants have been installed in rural areas of Islamabad, which are meeting domestic fuel needs of 20 houses.

The NGO Initiative for Rural and Sustainable Development (IRSD) has installed around 150 biogas plants with support from the United Nations Development Programme (UNDP) Small Grants Program. Some Regional Support Programs and NGOs have also included biogas among their projects: “Koshis” in Sialkot, Punjab, helped villagers to build over 200 biogas plants; “Green Circle Organization” is building community-based plants with funding from the Pakistan Poverty Alleviation Fund. Most NGOs received technical assistance from PCRET in the design of their plants. With some exceptions most plants are still installed on a pilot basis and have not been promoted commercially to any large scale. During the years 2005/2006, the Alternate Energy Development Board (AEDB) installed 1,200 family-size biogas plants to cover fuel needs of 1,200 households in the rural area of the Punjab province.

Most of the biogas plants installed in recent years were smaller household designs with 3–5 m³ gas production per day, compared to the larger plants constructed in the 1970s and 1980s. The biogas technology most commonly used in Pakistan is the

floating-drum design. The Chinese fixed-dome design was installed on a pilot basis but was reported not to be successful. Obviously due to poor construction quality, the Chinese dome design pilot biogas plants showed persistent leakage and seepage problems, and therefore, the gas pressure was reported to be low. Twelve fixed-dome “Nepalese design” biogas plants of Model GGC 2047 of 6 m³ were installed in the “*tehsil*” (sub-division) Pasrur of Sialkot District in partnership with the Punjab Rural Support Program (PRSP) and four plants of the same design were installed in different sizes of 8 m³ (2 units), 20 m³, and 35 m³ in Dera Ismail Khan in partnership with the Foundation for Integrated Development Action (FIDA) by the Rural Support Program-Network (RSPN) in June of 2007. FIDA was reported to have plans to continue supports to install biogas plants in its working areas. In 2006 SNV started to support a new nationwide biogas dissemination program for low-tech household biogas digester systems.

During 2002, a more efficient and cheaper “Thailand model” of a household biogas plant was installed at the Green Circle Organization (GCO) working model site to compare efficiency and cost-effectiveness of two models, the Thai and the formerly applied one. Transfer of the new Thai biogas technology and dissemination of information started in the Village Shirin Muaafe, *tehsil* Depalpur of Okara District. The results are that due to the proper dissemination of information, GCO have facilitated the farmers to install 80 biogas plants in the vicinity of the project area.

A governmental supported project on White Revolution “Dhoodh Darya” started in 2009 with 10 components with main thrust on development of milk pockets and establishment of milk pasteurization plants, infrastructure development of military dairy farms, bulk vending of milk, training and extension of Pakistan Dairy Development Company’s (PDDC) breeding program, and promotion of biogas units. It has already developed 48 community farms, trained a large number of farmers, and installed 825 medium-sized biogas units. The work started in the year 2009 for the establishment of community farms, biogas plants, large and small pasteurization plants, and bulk vending units, and training of master trainers will be continued up to the end of 2011.

Philippines Dr. Felix C. Maramba, an agricultural engineer by profession of the then Araneta University Foundation, introduced biogas technology in 1965. The today De La Salle Araneta University (DLSAU) was formerly known as the Gregorio Araneta University Foundation, which was established in 1946 as the Araneta Institute of Agriculture. The university specializes in Veterinary Medicine and Agricultural Sciences. He is the founder of the Maya Farm Biogas Model. In the early 1970s, the Maya Farm, a commercial piggery farm located 40 km east of Manila, has been the pioneer in the development of biogas technology. In order to obtain the necessary experience and to assess the suitability of different types of plants, demonstration models of Indian, Chinese, and European types were set up. The models were later modified and used as pilot plants. Biogas produced at the farm supplies 40% of the total power requirement of the farm and is used for home applications, cooking vats in the canning plant, fuelling of burners for heating and gasoline engines, running a feed mill, operating a 60 kVA electric generator and running farm vehicles. The organizations engaged in extension of biogas technology are the National Housing Authority, the Engineering Battalion of the Military, and the Department of Community Development. The Development Bank of the Philippine granted loans to farmers at low interest rates for the biogas project.

The Philippine NGO Rural Life Centre (PRLC) promoted a culvert-type biogas system in the early 1980s. The PRLC trains people from the government as well as from the private sector in the field of animal production and biogas technology. Many units of the model were copied and installed in selected villages but the continuity ceased because the PRLC project was terminated in the late 1980s.

The Philippine National Biogas Technology Extension Program in Key Livestock Areas was established in 1996 in cooperation with the Department of Energy and the Department of Agriculture where Cavite State University was designated as the National Biogas Centre. Since then, a number of local, regional, and national seminars, trainings, and workshops were conducted to promote the technology. Participants came from various sectors of the society: private individuals, companies, NGOs, agro-industry, and government agencies.

The Philippine Agricultural Engineering Standard PAES 413:2001 about Agricultural Structures–Biogas Plant was initiated by the Agricultural Machinery Testing and Evaluation Centre (AMTEC) under the project entitled “Enhancing the Implementation of Improved Agricultural Engineering Standards” which was funded by the Bureau of Agricultural Research (BAR) of the Department of Agriculture (DA).

Thailand Thailand was introduced to the biogas technology in 1950 by Kasetsart University (KU), which continues to be a cooperating agency even today. In 1960, due to poor hygiene and the need to improve health conditions in rural areas, the Department of Health (DoH) within the Ministry of Health (Sanitation Division) became involved, promoting biogas tanks as a sanitation technology.

The need to conserve energy dominated during the first and second oil crises between 1970 and 1980. It was then that the National Energy Administration (NEA) and the Department of Agricultural Extension (DoAE) started to introduce biogas programs for rural energy on small farms. By 1988, about 5,500 biogas plants were constructed, those being mainly 4 and 6 m³. In order to overcome the numerous technical and managerial uncertainties, an improved Biogas Programme in Thailand was implemented in September 1988. Responsibilities for carrying out its activities were with the Chiang Mai University (CMU) and with the Department of Agricultural Extension (DoAE) within the Ministry of Agriculture and Cooperatives. The German Development cooperation supported the program from September 1988 until December 1994 (Thai-German Biogas Programme). Several systems of all sizes have been constructed in the northern and western regions of Thailand, partly supported through loans from the Bank of Agriculture and Agricultural Cooperatives (BAAC) in Thailand.

Biogas Advisory Unit (BAU) at Chiang Mai University, with a grant supported by the government under The National Energy Policy Office (NEPO), launched the National Biogas Dissemination Program for the medium and large-scale livestock farms in October 1995. A target of 50,000 m³ biogas system within 6 years, starting from 3,000 and 7,000 m³ in the first and the second year, with another 10,000 m³ annually in the following years, is the goal of the program. The

program concept consists of two major parts: (1) the dissemination of small household biogas digesters (8, 12, 16, 30, and 50 m³ volume) under the responsibility of the Department of Agricultural Extension (DoAE) within the Ministry of Agriculture and Cooperatives and (2) applied research and development at CMU, including the provision of consultancy services for anaerobic wastewater treatment to specialized pig farms.

From 1995 until 2000, 70,000 m³ volumes of digesters had been built with support through the Energy Conservation Fund under the National Energy Policy Office (NEPO) in Thailand. The Energy Conservation Fund (through the Renewable Energy Programme) aims to provide financial incentives, as well as awareness campaigns, in order to promote the generation of methane gas from agricultural wastes. Only a few provinces with a high potential for biogas utilization (i.e., high concentration of suitable animal farms) will be selected for this program. Since 2001 the implementation was fully transferred to the responsibility of private contractors, as a regular business sphere in the field of environment protection (“commercialization” of the technology).

Vietnam Biogas technology has been introduced and developed in Vietnam since 1960. The history of biogas technology began in the South; the Department of Animal Husbandry conducted research on collecting methane gas from animal manure.

In the northern part of the country, biogas technology was introduced in 1964, when the Ministry of Industry started the first “Methane power station” in Bac Thai province. Between 1965 and 1975, Ha Noi, Ha Nam Ninh, and Hai Hung provinces also built biogas plants. These plants stopped functioning after a short time due to a lack of access to technology and management experience.

After the country’s reunification in 1975, it was one of the top priorities of the state research program on new and renewable energy until 1990. Within the framework of this program, there were many research projects focusing on biogas technology. The institutions participating in the program were the Institute of Energy, Technology University of Hanoi, Technology University of Ho Chi Minh city, Technology University of Da Nang, Can Tho University, and provincial

departments of Science, Technology and Environment. In 1976, the Vietnam Institute of Energy began researching “Fermentation for methane gas production.” From 1981 to 1990, there was renewed interest in biogas technology with the introduction of the National Research Program on New Energy Sources within the Institute of Electricity Science and Technology and international support from the Soviet Union, OXFAM UK, UNICEF, Sweden, and others. Institutes, research centers, colleges, army units, and individuals collaborated on biogas projects.

By 1990, about 2,000 small biogas units had been built in Vietnam with size ranging from 3 to 10 m³. Some of the most common types of biogas plants used in Vietnam include floating gas holding units, biogas units with plastic bags; fixed-dome brick biogas plants some with composite cover, spherical form digesters, Energy Institute type NL6 digesters, and household models KT1, KT2, and KT2B. In general, while all biogas technologies have advantages and disadvantages, biogas is the most suitable technology for livestock waste treatment. The first national workshop on biogas was organized within the frame of the National Program on New Energy Source. This workshop helped build momentum to advance research and development of methane gas and biogas technology in Vietnam. From 1991 to 2001, biogas technology developed rapidly with continued support from the Vietnamese government and international partners.

Since 1992, within the framework of the projects of the Ministry of Agriculture and Rural Development of Vietnam (MARD), polyethylene plastic bag digesters have been developed. Owing to low cost and simplicity of installation, this technology has been rapidly adopted and disseminated by the network of Agricultural and Forestry Extension, Association of Vietnam Gardeners (VACVINA), and some local private actors. It is estimated that up to one million of such simple very low-tech plastic bag digesters may exist today.

By the end of the 1990s, the Centre for Rural Communities Research and Development (CCRD) further developed the original model and has successfully designed and introduced a new advanced biogas model, named “Hybrid Technology Bio-digester with Automatic Scum Control” or VACVINA Bio-digester, in order to help farmers to apply biogas technology, generate biogas for cooking, reduce workload for

women, actively treat waste from livestock, protect the environment, and reduce pressure on forests. In 2000, the Toyota Foundation provided support to enhance capacity building of VACVINA’s staff and to disseminate the VACVINA biogas model nationwide. More than 300 technicians had been trained on all necessary skills on building VACVINA bio-digesters and more than 750 biogas demonstration models have been built in the 61 provinces of the country. In conjunction with CCRD, from 2006 to 2009, ETC Foundation (Netherlands) and Research Centre for Energy and Environment (RCEE) started a development strategy for Enabling Access to Sustainable Energy, including the VACVINA biogas model in a market orientation approach in Thanh Hoa province. In 2011, there are more than 11,000 VACVINA biogas plants constructed by farmers themselves with technical assistance of trained technicians. MARD in Decision Nr.4414/QĐD-BNN-KHCN of October 18, 2002 recognized this initiative and allowed its application nationwide.

Also in 2002, MARD issued standards for small-scale biogas systems (10TCN 492÷499-2002 and 10TCN 97÷102-2006). In 2003, the “Support Project to the Biogas Program for the Animal Husbandry Sector in Some Provinces of Vietnam” has been initiated. The goal of this project was to develop a commercially viable and market-oriented biogas industry and contribute to avoiding the use of fossil fuels and biomass resource depletion. The Department of Livestock Production, MARD, and the Netherlands Development Organisation (SNV) are the primary implementing agencies for the project. By the end of 2008, the program provided training for 500 provincial and district technicians, 700 biogas mason teams, and organized thousands of promotion workshops and trainings for biogas users. By the end of 2009, the project has supported construction of over 78,480 biogas plants and received recognition for its efforts by winning the Ashden Energy Award. The project aims to develop around 167,000 low-tech biogas projects in 63 provinces throughout Vietnam by end 2012.

Under the World Bank funded and MARD implemented Livestock Competitiveness and Food Safety Project (LIFSAP) there is also a small household biogas component, running from 2010 to 2014. The project supports up to 12 provinces which will meet the eligible criteria established by MARD,

including: (1) the density of livestock farms and livestock populations, (2) livestock market share, (3) the availability of livestock support infrastructure, and (4) a viable policy to support the development of livestock production. The total grant amount per biogas plant is US\$ 200 to support both the construction of the biogas plant and for additional bio-security measures. Without taking into account program costs the funding will be enough to support the construction of a maximum of 20,600 biogas plants.

In addition, the Asian Development Bank loan financed “Quality and Safety Enhancement of Agricultural Products and Biogas Development Project” (QSEAP) commenced in 2010 and will end in June 2015 and covers 16 provinces in the country. The project’s purpose is to build 40,000 biogas plants with the provision of subsidy to at least 20,000 households, and credit to households and farms raising animals. Up to now, the project team received initial results: training 276 technicians, 359 skill masons, and constructing 6,953 biogas plants of small scale of model KT1 and KT2 in 16 provinces.

Parallel to the agricultural-dominated biogas activities, the National Rural Clean Water Supply and Environmental Sanitation Program is targeting to promote the construction of 1,000,000 household biogas-sanitation plants or at least toilet connection to existing agricultural biogas plants in the period 2000–2020.

Africa

The first aid-driven approach for biogas extension in Africa dates back to the early 1970s, when politicians and decision makers from different African countries visited India and were fascinated by the biogas technology. The Indian Government, and later also the Chinese Government, showcased their specific biogas technologies in different African countries in such a way that a foreign expert team built a few institutional biogas digesters and trained numerous people in design and construction only. As no funds have been made available for long-term commitment and dissemination programs, these approaches led to failures in operation, management, and even construction copies, which are scattered all over the continent, particularly in agricultural institutions. At this time, the main actors in potential biogas dissemination programs

were identified in the governmental agricultural or energy research institutions of the respective countries. But a deeper rooted operational and managerial know-how or commitment could not be developed or conserved.

In the late 1970s, triggered by Ernst Friedrich Schumacher’s (1911–1977) “Small is Beautiful” (first published in 1973) appropriate, simple technologies entered the arena of development work in the South. Not northern high-tech, but innovative, affordable, simple, and traditional technologies were believed to be the remedy for the development and technology gap between industrialized and developing countries. This resulted in a cross-sectorial scheme of many development cooperation institutions accompanying and supporting the development and dissemination of biogas technology in Latin America, Asia, and Africa. Industrialized countries neither had sufficient experience nor appropriate technologies to build on in developing countries. Rather, this experience was identified in India and China and became an issue for a South-North-South transfer.

In 1980, the German Federal Ministry for Economic Cooperation (BMZ) instituted a “Biogas Extension Programme” (1980–1993) as part of the German development aid. It was prompted by the realization, and by analyzing the results of the first German development supported biogas projects in Cameroon in 1978, and short-term consulting work done between 1977 and 1980 in India and China, that biogas extension requires an integrated approach. After understanding the reasons for the failures in the past, it was realized that compromises in technology quality could not be accepted. Only proven designs with good building material were used. Piping was changed to galvanized steel or HDPE pipes only, instead of garden hoses and gate valves, which both leak after a short time.

Prepared in October 2005 in Beijing as a Chinese-Netherlands-German effort, and based on the success in some Asian countries, in May 2007, representatives from 27 African countries met in Nairobi, Kenya, to formally launch the “Biogas for Better Life Initiative.” Since then, a number of country biogas program pre-feasibility and feasibility studies have been completed by the Netherlands Development Organization (SNV) and the German International Cooperation (GIZ), and programs are already being launched in Rwanda,

Uganda, Burkina Faso, Senegal, South Africa and Ethiopia. The group discussed important aspects of developing and implementing national biogas programs including sanitation, gender integration, technology, costs, program structure and management, financing and subsidy structure, carbon financing, and marketing and communications.

A Foundation “Biogas for Better Life: An African Initiative” has been established on February 28, 2008, in the Netherlands to provide this initiative with a legal basis. This allows the initiative to sign agreements with sponsors to support the initiative financially; to enter into agreements for the implementation of national biogas programs, such as the one for Rwanda; to support research and development and knowledge management in biogas; and support all the components of the Initiative Business Plan 2006 till 2020. Until recently, this was done on an individual and ad-hoc basis with individual sponsors such as Shell Foundation, International Humanist Institute for Cooperation with Developing Countries (HIVOS), German International Cooperation (GIZ), the Netherlands Development Organization (SNV), Dutch Ministry of Foreign Affairs (DGIS), Practical Action, German Bank for Reconstruction and Development (KfW), and many others.

Today, “Biogas for Better Life” is an African initiative that aims to improve the health and living conditions of men, women and children; to reduce the use of firewood and charcoal for cooking; to improve soil fertility and agricultural production; to reduce greenhouse gas emissions; and to create new jobs through the development of a robust biogas-related business sector throughout the African continent.

The initiative will identify “pockets of opportunity,” and initially focus on programs in African countries with the strongest market potential. The initiative aims to install two million household-level biogas plants in 10 years. The ultimate objective is to develop a sustainable, commercial biogas sector, which will in turn improve the lives and livelihoods of families in Africa. The initiative will foster partnerships and knowledge exchange, provide leadership and experience to developing and implementing national programs, stimulate further technology and market-based research, and help identify and develop financial resources for the biogas programs. Further extension is

planned soon to Kenya, Mali, Zambia, Niger, Ghana, Malawi, Lesotho – where biogas technology is already successfully disseminated since 2003, namely, Swaziland, Sudan, and the West African countries.

Algeria French researchers in North Africa, between the years 1940 and 1951, are reported to have made extensive efforts to develop so-called dry-fermentation methane digesters based on straw and manure. There is ample literature on their work in French journals. G. Ducellier and M. Isman developed the design and prototypes in the then French North Africa already as early as 1937. The technique of Ducellier and Isman, at the Institute of Agriculture in Algeria, was the first ever batch-fermentation system with pre-aerating (pre-composting) of the waste mass (straw-manure-organic waste) for 20 hours in order to raise the temperature to 70–80°C. The wastes were then flooded with water and liquid manure, and the anaerobic process commenced. A floating gasholder covered the tank and straw had been packed to a thickness of 40 cm out around the walls to serve as insulation. In unmixed tanks of several 10 of m³ of size the biogas production was 70–90 m³/t wastes capacity, averaging 0.4 m³ per tank volumes/day for the duration of the fermentation.

Burundi The first national biogas program, started in 1984, was supported by German Development Cooperation (GIZ) and established in cooperation with a Belgium research project and a Chinese training program for biogas constructors, using livestock manure, toilet wastewater, and human excreta as feedstock. A countrywide biogas school sanitation project with World Bank support was carried out from 1985 to 1989 led by the Ministry for Energy and Mining. Several projects were initiated by the GIZ Biogas Dissemination Programme, which started in 1984 in the eastern region of Cankuzo. In 1988, this project was integrated into the “Special Energy Programme” and was stopped due to civil war in 1992.

After first experiences with family-sized biogas plants, the project team started in 1987 to build medium-scale biogas-sanitation systems (100–250 m³) to treat human excreta and gray water of boarding schools. Private contractors were responsible for the plants. The training of craftsmen, the establishment of a service system, and the setup of material credit funds

were to provide the basis for a self-reliant dissemination concept. By 1992, 206 small-scale biogas plants, and 84 institutional medium-scale biogas-sanitation plants (tunnel and fixed-dome plants) had been constructed. Six out of ten households examined under the Biogas Survey in 1992 used liquid slurry as fertilizer. Learning from Burundi, biogas units were also constructed in Bukavu/Congo.

Ethiopia Biogas technology was introduced to Ethiopia in 1977 through the German NGO Bremen Overseas Research and Development Association (BORDA) with German development cooperation support. In the years 1986 to 1988 in 21 counties (Woredas) west of the Amhara State, Indian design floating-drum plants with a volume of up to 8 m³ have been financed and built by the Rural Technology Promotion Centre Bahir Dar. In a bilateral project, German development cooperation supported the construction of 120 biogas plants between 1999 and 2002 by informal private firms and the local NGOs.

Since 2008, the Netherlands Development Organisation (SNV) supported a pilot phase of a National Biogas Program Ethiopia (NBPE) aiming to build within 5 years up to 14,000 low-tech fixed-dome biogas plants in four regional states. It is expected to develop a private and competition-based biogas industry. The NBPE promotes only plants of 4, 6, 8, or 10 m³, thus limiting subsidies to farms with a maximum of 100-kg manure per day, corresponding to approximately 20 local cattle.

Kenya First attempts to use biogas technology to obtain energy from coffee pulp go back to the mid-1950s. In the following 25 years, the private entrepreneur Hutchinson sold more than 100 plants of various types mainly to large-scale farmers. In 1983/1984, Germany supported the training of craftsmen in the construction of biogas plants; as a result, 40 biogas plants were built in the Meru region. Until 1988, extension of dissemination efforts into other regions led to about 250 floating-drum plants in various regions, mainly for energy supply. Following the philosophy that an extensive project apparatus with a solid financial background has time limitations, emphasis was placed from the very beginning on private entrepreneurs for the construction of the plants and the

provision of biogas accessories. Only demonstration plants in new project areas were subsidized by the project; in other cases, biogas customer pays the market price for his plant.

From 2006 until June 2011 with funding from the European Union dissemination measures for resource-friendly technologies succeeded in the installation of more than 200 low-tech biogas plants. Since 2003, and jointly coordinated in one program, Germany and the Netherlands are supporting the integrated biogas development in the agricultural sector. A national biogas technology standard is under preparation since 2011.

Lesotho Since 2003, after Food and Agriculture Organization of the United Nations (FAO) and China supported pilot experiences during the 1980s, a digester design that has undergone various adaptations in African countries under the umbrella of the German Development Cooperation (GIZ) has been implemented in Lesotho by a newly launched NGO, Technologies for Economic Development (TED). Since then, it is widely proven that biogas technology can work successfully in the Mountain Kingdom.

TED was created as a successor of the *Lesotho Biogas Technicians Self Help Group*. With the TED design, incorporating household wastewater into the feeding material for anaerobic digestion, a solution for the most pressing problems especially for urban households was identified: lack of water for irrigation, expenses for construction, and maintenance of septic tanks.

In cooperation with TED, more than 300 digesters of varying sizes were built and most of them are still in operation. The TED bio-digester works well on household, institutional and settlement level as well as for an industrial abattoir with its special feedstock. Today, biogas in Lesotho is a technological package where wastewater and other organic matter are treated in a bio-digester producing gas as an energy source and water is further purified as fertilizer or sludge as soil conditioner or fertilizer. The technology follows the concept of DEWATS (Decentralised Wastewater Treatment Systems) as developed by BORDA (Bremen Overseas Research and Development Association), however, with special focus on energy generation that substitutes up to 20% of a household's cooking fuel demand.

The system is found appropriate not only for the capital Maseru and the district towns as many households and institutions have serious problems, and high cost burden with the disposal of their sewage; the TED system does not cater only for water-borne sanitation but also for dry systems. Peri-urban farms start nowadays to be interested in the system, too. TED provides 12 months after-sales service free of charge, a paid life-long after-sales service, and trains owners on how to care for the system. Currently, about 25 units are constructed per year, totally financed by the individual clients.

Morocco The dissemination of biogas technology focused on the Souss-Massa region. Initially three fixed-dome plants were rehabilitated, and three 12 m³ plants, five 20 m³ plants, and two 85 m³ plants were constructed with the main purpose of electricity generation. By 1998, 80 digesters have been installed (10–100 m³) with a total volume of 2,000 m³.

In 1995, a biogas plant was constructed at the wastewater treatment plant in Ben Sergao to use sewage sludge for biogas production. Since 2008, German Development Cooperation (GIZ) started to support low-tech biogas installations for wastewater and manure treatment.

Tanzania The history of biogas dissemination in Tanzania dates back to 1975 when the Small Industries Development Organisation (SIDO) built 120 floating-drum biogas installations up to 1984. In 1982, the newly created Centre for Agricultural Mechanization and Rural Technology (CAMARTEC) took over the promotion of biogas in the Arusha area. In 1983, German Development Cooperation (GIZ) introduced a biogas extension service and disseminated biogas plants mainly in this region where favorable agricultural and socioeconomic conditions let expect a high dissemination for biogas plants. The project worked with a standardized plant design, clearly defined administrative procedures, and offered a warranty of 2 years and technical advice to the users in the villages. In 1984/1985, household biogas plants were offered with digester volumes of 8, 12, and 16 m³, and in 1990, the program included standardized plants of 12, 16, 30, and 50 m³ for households and institutions as well as a special “toilet biogas plant” for institutions.

Request which could not be covered by the standardized range of plants and services and which required additional research and development work had to be financed completely by the customer. The program introduced the *biogas unit concept* defining the *unit* as (1) an appropriate stable with solid floor, (2) a pressure tested piping system, (3) gas use appliances, and (4) a slurry utilization system adequate to the individual farm. The costs for a biogas unit increased from around TSh 300,000 in 1989 to TSh 400,000 to 7,000,000 in the beginning of the 1990s. Despite this, the number of units constructed until 1992 increased to about 400. Between 1990 and 1993 CAMARTEC conducted four international training courses with national and international participants and trainers, leading to the popularization of the CAMARTEC design in Ethiopia, Kenya, Uganda, and Thailand.

The dissemination strategy and project structures underwent decisive changes around 1990 as a result of transfer of the project to the counterpart organization. German experts also studied large-scale application of industrial biogas units for sisal industry; the first unit in Tanzania was constructed in 2007 by a Chinese-German consortium supported by the United Nations Industrial Development Organization. Since 2008 Tanzania established a nationwide new biogas dissemination program with SNV support.

Tunisia Biogas was introduced in the Sejenane region in 1982 as an 11 m floating-drum plant. In 1986, the first fixed-dome plant (6 m³) was built. With German Development Cooperation (GIZ) support, in 1989, non-functioning plants in the region were rehabilitated and 10 new plants built. The first technicians received training in Burundi and Germany. A biogas laboratory was installed at the Technical University Tunis in the framework of German Development Cooperation (GIZ). The activities focused on the modification of the technical aspects (mainly gas appliances), training measures, and slurry experiments under local conditions. Between 1990 and 1992, 16 more biogas plants were constructed. The first solar-heated low-tech fixed dome digester was reported to be operated by the Technical University Tunis. Then China took over the activities, supporting Tunisia until 2003 with the training of biogas technicians and supporting some more

biogas plant construction. Since 2011, World Bank is strongly supporting the new biogas development for large dairy farms in Tunisia.

Rwanda In Rwanda, biogas technology is quickly catching up through the efforts of Kigali Institute of Science Technology and Management (KIST), where several former counterparts of the Germany supported Project in Tanzania (with CAMARTEC) are working. KIST has designed and built a 150 m³ fixed-dome digester in Cyangugu prison that is fed with waste generated by 1,500 prisoners. This digester produces methane gas that caters for 50% of the cooking needs for the 6,000 inmates. KIST has also solved the sewerage and hygiene problem at the school “Lysee de Kigali” by providing a 25 m³ fixed-dome digester connected to six bio-latrines. The biogas produced is used as cooking fuel for 400 students and for operating Bunsen burners in the school laboratories. KIST was also supported for many years by Chinese experts to introduce biogas digester design-based decentralized wastewater treatment systems (DEWATS). Since 2007, Rwanda established a SNV-supported National Biogas Program with the target of 14,000 plants in 5 years. China is once more engaged in the Rwandan biogas sector since 2009, and has promoted since then at least 100 prefabricated composite biogas plants, which had been delivered from China.

Central and South America

In Central and South America, biogas plays a role within the renewable energy sector, too, although many countries are still missing in the list of advanced renewable energy technologies and dissemination.

Belize The first project in biogas technology started in 1988. It evolved from a Caribbean biogas dissemination program carried out by the Caribbean Development Bank. German and local biogas consultants and biogas technicians have been active in the region constructing three floating-drum plants following the BORDA model within the Caribbean Technology Consultancy Services (CTCS). As neither the market forces could take up biogas technology nor could independent dissemination structures grow, the program continued in 1989 along the lines of experience gained

during biogas activities in the Caribbean and Nicaragua – to anchor biogas-specific, national know-how in a local and regional dissemination structure. With this background experience and the financial, personnel, and material support of the Caribbean Biogas Dissemination Program, a German integrated expert under local project contract and a Belizean expert have been employed to build up such a structure in cooperation with the state Central Farm and to demonstrate the high performance and efficiency of biogas technology. In 1991 the CAMARTEC model from Tanzania was introduced. In comparison to the high input of material and work in plants used previously (reinforced steel vault and fundament), a cost reduction of approximately 15–20% was achieved. Since 1993, at least 20 plants have been built (of these, five are constructed at institutions, 13 at household, and two are medium-sized farm biogas plants). The target group for the household biogas plants so far consisted of farmers involved in commercial pig production. Low-tech household biogas system users in Belize mostly own 5–40 pigs.

Nowadays, with support of the European Community and through the partnership with the Ministry of Agriculture and Fisheries (MAF), the Inter-American Institute for Cooperation on Agriculture (IICA) and the Belize Audubon Society (BAS), small- and medium-sized farms are benefitting from biogas installations as a low-cost alternative and renewable energy source.

The first phase of biogas digester implementation was initiated by a “training the trainer” course conducted by the EARTH University in Costa Rica. This training received a follow-up by means of the installation of biogas digesters at Central Farm and Yo Creek Agricultural Stations, San Antonio and San Marcos in the Cayo district, Maskall and Crooked Tree in the Belize district, and San Antonio in the Orange Walk district. The promoted low-tech biogas digester (called “the worm”) is a tubular structure made of polyethylene plastic which is placed in a pre-dug pit. The system serves for anaerobic fermentation of organic materials such as manure from pigs, cattle, sheep, and other organic wastes, thus reducing the risk of pollutants and contaminants in the environment. Farmers understand the opportunity to obtain alternative fuel and organic fertilizers, reducing the need for chemical

fertilizers and significantly reducing the cost of production.

The construction of this type of biogas digester is quite simple; it is made of a tubular plastic bag and other basic parts could be found in local hardware and mechanic shops. These basic parts include a few feet of PVC pipes, a few elbows and connections, used bicycle tubes and recycled buckets.

Bolivia In 1986, the GIZ started as project in cooperation with the Universidad Mayor de San Simon (UMSS) in Cochabamba to disseminate biogas technology. Until 1989 these activities were part of the supra-regional GIZ Biogas Dissemination Programme. From January 1990 to the end of 1992, the biogas activities were continued as a component of the Bolivia Special Energy Program. By consolidating biogas technology into the Cochabamba Department and into the general background of national energy and landscape planning by means of the National Biogas Network, the aim was to integrate “biogas technology into the agricultural production process” so that the “destruction of agricultural ecosystems” could be curbed and “energy and organic fertilizer” could be produced in a decentralized manner. A total of 27 plants, nine of them in the Cochabamba area, have been constructed by different organizations already before the German support started.

In 1988, the German Development Cooperation (GIZ) purpose was defined as “the creation of fundamentals on which Bolivian institutions will be enabled to disseminate biogas technology extensively through training and construction of demonstration plants.” Loans, training, and the improvement of project management were to allow a high-performance dissemination structure. Emphasis was given to the integration of the technology into local, regional, and national socio-economic structures and on the dissemination of “Integrated Farming Systems.” The biogas plants were mainly understood as “fertilizer-producing plants” making a significant contribution to the strengthening of intensive animal husbandry and agricultural production.

After constructing the first four solar-heated biogas plants in the 1980s in the Bolivian highlands at 4,000 m altitude, the project regions of higher altitude were declared unsuitable for low cost, but not for low-tech

biogas plant dissemination. Therefore the biogas office concentrated more and more on the migration regions in the tropics with an inferior infrastructure. In these regions about 35 plants were built between 1989 and 1992. A survey carried out by the biogas office has identified potential, particularly in the area of Santa Cruz de la Sierra, in the field of industrial and communal sanitation. After having built a UASB (up-flow anaerobic sludge blanket) digester at the Palmasola prison, knowledge about anaerobic wastewater treatment technology was established in local NGOs, supported by integrated experts from Germany.

As Bolivian NGOs continued with successful biogas extension of 250 PVC-plastic plants from 2002 to 2005 in high altitudes, in a second attempt by German and Netherland development support, a new program was launched in September 2005 with the goal to supply 575,000 people, corresponding to 6% of the Bolivian population, with modern renewable energy. Donors like the World Bank, International Fund for Agricultural Development (IFAD), and the Inter-American Development Bank (IADB) evinced interest to participate in this program. With the approach of process consulting and human presence on the ground, the German Development Cooperation (GIZ) took an important role as adviser of the national biogas program.

Since 2007 about 250 low-tech and low-cost PVC-plastic bag sausage-shaped biogas plants of 8 m³ have been disseminated in Alti-Plano villages at 4,000 m and in the temperate area of Cochabamba. Packed in earth wall bricks and covered with straw roofs for insulation, they produce enough biogas to provide cooking fuel for 4–5 hours per day. This design receives attention also in the tropical areas and is now promoted as low-tech and low-cost biogas plant.

Columbia In May 1985, the Special Energy Program Columbia located in Barranquilla started. The project concept focused on “investigation of the possibilities of producing and using biogas” in Valle de Cauca. Corporación Autónoma Regional del Cauca (CVC) was the executing organization. A German long-term expert has been integrated into the project from November 1985 to 1992. During the first project phase, the central problem was the pollution of water resources, which should be reduced by the

dissemination of biogas technology. Project activities were characterized by research and development; investigations were carried out on the use of slurry generated in biogas plants. In 1989 the project goal switched to a clear contribution to the improvement of the rural energy situation and the conservation of water resources by the use of biogas plants. This phase was then characterized by rehabilitation of non-functioning biogas plants and the setup of a dissemination structure. The construction of demonstration plants on selected farms aimed at introducing biogas technology in the rural region. Further involvement in the agro-industrial sector was suspended due to the sector's complexity although initial investigations on anaerobic digestion of agro-industrial wastewater had been carried out. Between 1985 and 1992, a total of 25 biogas plants were built, including a floating-drum plant (BORDA type), a tunnel plant, various fixed-dome plants, a balloon plant, and a UASB (up-flow anaerobic sludge blanket) plant.

When the international support came to an end in 1992, standards of biogas plants existed for four fixed-dome plants of 14–48 m³ and three fixed-dome plants of 67–115 m³ with a separate gasholder. In line with the heterogeneity of biogas users' agricultural household and farm systems, the integration of biogas technology into agricultural and farm systems required to be highly flexible. The plants were mainly built for medium-sized and large-scale pig and cattle farms with 20 and 2,000 animals. The heterogeneity of the farms was also reflected in the pattern of utilization and the condition of the plants.

Since 1986, with Belgium and Netherland support, industrial size biogas technology was developed as treatment and reuse system for agro-waste in the tropical regions. During the first years (1986–1989), biogas digesters have been classified as farming intensification technologies. These reactors transformed liquid manure into organic fertilizer; the generated biogas was just a sub-product. This intensification was also applied to the flower agro-business where flower wastes were fed into biogas digesters. Since 1989 anaerobic systems for agro-industries and municipal sewage (UASB technology/anaerobic filter/contact biogas digester/covered anaerobic lagoons) have been built. The biggest municipal wastewater anaerobic treatment plant was installed in Bucaramanga for 100,000 people

equivalent (PE). Since 2005, due to rise of crude oil prices and the implementation of the Kyoto Protocol, activities have shifted toward biogas capture and use.

The low-tech biogas digester technology exists in the country only on small scale, although with a trend to expansion, particularly in suburban areas. Local craftsmen in partnership with NGO have constructed many of these biogas digesters.

Cuba Supported by India, Cuba started its national biogas program in the 1970s; in a second attempt at 1990, biogas was rediscovered with German and Chinese support. Having created a national biogas expert group in Santa Clara in 1994, the current national biogas expert association was formed under the Ministry of Agriculture. Since 1992 international biogas advisers from Germany, Canada, and China have worked with Cuban counterparts supported by Germany, EU, UN-agencies, international NGOs from Canada and the Netherlands, or as part of the Chinese development cooperation with the Ministry of Sugar, the Ministry of Agriculture, and the Ecumenical Council of Cuban Churches. Industrial-sized biogas plants were installed at distilleries, and for sisal and sugar processing wastewater, and for dairy farms and pig breeding farms of about 20,000 animals (e.g., Soroa Farm). In addition to other donors, supported by German, Canadian, and Spanish NGOs, small-scale low-tech biogas digesters, such as fixed-dome plants, floating gasholder plants, tubular PVC and PE bag biogas plant designs, and prefabricated glass-fiber (composite) biogas plants, were jointly developed and locally adapted.

Today (2010) about 1,000 biogas plants are operating throughout the country, mainly low-tech PVC-plastic tubular “sausage” plants and fixed-dome plants; target groups for these plant types are suburban and rural households with pigs, vegetable production, and decentralized small- and medium-scale dairy farms. Biogas is used only for cooking, due to commonly experienced energy shortages. Local institutions nationwide, with an umbrella of a National Biogas Association, are planning to construct yearly about 400 low-tech biogas plants.

Jamaica A document on the Biodigester Septic Tank (BST) was prepared in 2000 by the Scientific Research

Council of Jamaica (Ministry of Land and Environment, 2002) and presented to the Ministry of Commerce and Technology, the Ministry of Health, and the Ministry of Land and Environment/Ministry of Water and Housing for approval to be used as the system for future on-site sewage treatment for housing developments. In the following years a wide range of requests were received from housing developers to utilize the biogas technology which has been developed with German support for the on-site treatment of domestic sewage for urban, suburban, and rural housing, thus replacing septic tanks and soak-away pits.

Nicaragua After a pilot Biogas Dissemination Program supported by the German Development Cooperation (GIZ) in the early 1980s, Stichting Nederlandse Vrijwilligers – Netherlands Development Organization (SNV) restarted pilot activities to prepare a national biogas program in Nicaragua and Honduras in 2010.

Challenges, Success and Failures

Challenges, success and failures of any technology are always linked to a number of factors and influences of quite a variety of characteristics. In the case of “biogas technology,” given that applications occur worldwide under a range of frame conditions that cannot be easily compared, the influencing factors for success and failures are shaped by researchers, housewives, farmers, engineers and technicians, economists and politicians, bankers, energy suppliers, donors, hardware dealers, masons, and plumbers – just to name a few.

Therefore, the following chapter picked one example – the case of a pure market-oriented dissemination approach performed by a non-profit non-governmental organization in Lesotho, southern Africa. The challenges, success, and failures are analyzed against the overall dominating issues of sustainability.

Social and Cultural Sustainability

In order to achieve social and cultural sustainability of the promoted wastewater treatment technology in general and the installed Biogas/DEWATS systems in each specific case, TED, the Lesotho based Non-Governmental Organization “Technologies for Economic Development” applies social marketing principles adapted to sanitation requirements. The

strategy is based on three pillars: (1) stimulating demand, (2) private sector involvement in the supply chain, (3) social status. Following the guideline “Social marketing works to help people change their behaviors positively,” TED engages also in hygiene education, sanitation awareness raising, and sanitation marketing at all levels in Lesotho and abroad.

The creation of a sustainable sanitation market involves five “P”s: (1) product, (2) price, (3) place, (4) promotion, and (5) people, whose quality of life is directly influenced by the improvement of sanitation and hygiene.

Up to now, TED’s Biogas/DEWATS product has several “unique selling points,” as the NGO is still the only national organization to offer a real alternative to a conventional septic tank. Price comparison between the conventional on-site wastewater treatment system and Biogas/DEWATS results currently in lower investment costs for the conventional system, but in significantly lower operational costs for Biogas/DEWATS. Given the specific geophysical context of Maseru and its growth rate into peri-urban hilly areas, the connection to centralized sewer lines and wastewater treatment plants is for most of TED’s clients just not possible.

The sustainable social and cultural integration of TED’s biogas-sanitation system is also enhanced by the strong involvement of the future system owner in the decision on where to place the treatment system for the household’s waste water and the technology choice on reuse options. Also, wherever possible, already existing septic tanks and VIP latrines are integrated into the new design of the treatment system. Due to these close and personal relations with its clients, TED’s promotion strategy relies on “word of mouth” and clients’ testimonies to interested households.

In cases where communities (villages, schools, orphanages) ask for upgraded sanitation systems, TED informs the communities about different options, including urine diversion dry toilets. Urine diversion technologies and Biogas/DEWATS could be successfully combined.

Working closely with local partners at all levels TED spreads the message about the importance of sanitation, hygiene, and water for human well-being to different groups applying appropriate information and

education material. Local authorities, civil society organizations, and media form already part of the still informal sanitation network that TED intends to set up in Lesotho.

Economic and Financial Sustainability

The level of sanitation infrastructure in Lesotho is generally very low; a decentralized approach to sanitation services is a must. Biogas/DEWATS is one alternative to septic tanks in Lesotho. Wastewater naturally produces biogas and purified water that still contains plant nutrients for reuse in the garden. Owners save money because they do not have to call (and pay) a truck to empty the septic tank every year or even in a very much shorter period; they can use the biogas for cooking, and they can use the water for irrigation, thus reducing the fresh water bill. The money saved within a reasonable time (some owners calculate a maximum of 3 years as period of internal return rate) can be used for further investments to develop the local economy.

The costs for a biogas digester and related wastewater posttreatment steps are divided into production costs, running costs, and capital costs:

- Production costs include all expenses necessary for the erection of the plant (e.g., land, excavation work, construction of the Biogas/DEWATS, piping, and gas utilization system). The construction costs comprise wages and material. They depend on size and dimensioning of the biogas unit, amount and prices of material, and the labor.
- Running costs occur in some cases more often and in some cases rarely; they could include feeding and operating of the plant; supervision, maintenance and repair of the plant; storage and disposal of the slurry; gas distribution and utilization, and administration. The running costs of a biogas plant with a professional management are just as important as the construction costs, for example, for operation, maintenance, expenses for painting, service, and repair.
- Capital costs consist of redemption and interest for the capital taken up to finance the construction costs. It has to be mentioned that many customers provide themselves with, e.g., building material to cut their costs; therefore, just a few have to borrow money. In calculating the depreciation, the

economic life span of plants can be taken as 15–20 years, provided maintenance and repair are carried out regularly. The money, which is saved by using “waste” as energy source and irrigation water, needs to be calculated for each specific case.

TED’s clients have various problems and therefore various reasons why they want to have a Biogas/DEWATS. That is why the “real” investment costs can be higher than the “real” outcome costs. But the problem, for instance a septic tank, which is always overflowing, is solved. Additionally, it is true that one saves a lot of money by having this technology. There is just the question if the client can furnish the start capital to invest in this technology.

Environmental Sustainability

The following analysis refers to international experiences:

- Wastewater and manure are naturally treated by bacteria, which upgrade wastewater and stabilize sewage sludge. The system improves the fertilizer quality of human and animal waste.
- It reduces the greenhouse gas emissions by using the produced biogas.
- Protected areas or the ecosystem are not affected because the construction is realized close to villages. As the system is mostly underground, the landscape is not damaged or negatively influenced.
- The treated water – still containing plant nutrients – should be (and is) reused for irrigation.
- Where biogas is an alternative to fossil-based fuels, it is, on a national level, considered to improve the balance of payments since less oil products have to be imported.
- On the individual level, system owners save valuable fresh water resources by using treated wastewater for irrigation; in addition, they do not need mineral fertilizer because the irrigation water still contains valuable plant nutrients.

Technical Sustainability

Low-tech biogas plants are related to low-volume efficiency; therefore, simple design and low-cost construction materials are required to compensate this disadvantage with larger digestion volumes, multiple

step treatment system, and even posttreatment steps – if sanitization requires. Therefore, creative solutions have to be developed by the designers to integrate these required volumes in the given space, often solved by underground constructions, cylinder designs or round shape design, which allows also construction material economy combined with optimal strength. Local service structure must be established for maintenance, spare parts, and repairing. In order to assure technical sustainability and continuous updating of technical staff, TED Lesotho applies the following approaches:

1. To be integrated into worldwide networks and close cooperation with technology and research partners like Bremen Overseas Research & Development Association (BORDA), University of Science & Technology Beijing–Centre for Sustainable Environmental Sanitation (USTB-CSES), and Water and Sanitation Association of Zambia (WASAZA).
2. To offer – in collaboration and consultation with cooperation partners – service packages to integrate the technology into an environmental sanitation concept. This includes, e.g., school sanitation, community-based sanitation, and sanitation systems for hospitals, hotels and tourism resorts, military camps, and for agricultural enterprises.
3. To include Research & Development into implementation in order to achieve safe upscaling of implementation; R&D includes the following topics (list not exhaustive): (a) sanitation & renewable energies; (b) sustainable environmental sanitation, and (c) agriculture & livestock. Regular monitoring of the system performance and external evaluation of the results by academic cooperation partner support these R&D activities. TED thus offers researcher opportunities to gain experience in reuse-oriented wastewater treatment systems under Lesotho-specific conditions.
4. To train system owners and operators and to offer after-sales services: Well-informed system owners and operators ask only in very critical situations for special maintenance activities to be provided by TED staff. Experience shows that owners, understanding that Biogas/DEWATS functions due to a well-maintained biology of microorganisms, are operating their wastewater treatment system throughout the

years without any problem, and without requiring additional maintenance support. During the first 12 months after construction, TED provides training and accompaniment to the owners and operators (in the case of community, school, or enterprise connected systems) in order to familiarize the responsible person with all relevant details to maintain a successful wastewater treatment process for biogas production and irrigation water reuse.

Lessons Learned

TED's experience and "success story" shows that there are acceptable, affordable, and environmentally safe sanitation technologies based on anaerobic digestion, already successfully installed in urban settlements in Lesotho. Given the fact that TED is implementing Biogas/DEWATS without any subsidies but fully paid by the customers, it is clear that a sanitation market is viable. Sanitizing wastewater on the compound, making it fit for irrigation, saving valuable drinking water, and encouraging home gardening especially in an HIV & AIDS suffering country clearly helps to improve the living conditions of the population. Turning organic waste (solid and liquid) into biogas for cooking is an important measure for climate protection, climate change mitigation, and resilience.

Challenges encountered and relevant for the way forward are craftsmanship's quality, expertise in Biogas/DEWATS construction, ownership, and how to cope with the increasing demand. TED's way of dealing with these challenges is and was always developed in a very pragmatic manner due to its characteristics as a nonprofit-making NGO in a country with an endless number of constraints and limitations. The following overview should be read as an outline for "lessons learned" on how to upscale implementation of "biogas for sanitation" purposes:

- **Craftsmanship's Quality:** TED engages in continuous quality control of its construction staff. In cooperation with international partners, quality parameters have been established, in-house training is carried out, and a quality management system related to Biogas/DEWATS construction is in place.
- **Expertise in Biogas/DEWATS construction:** Considering the limited labor market for specialized

technical professionals in Lesotho, TED encounters difficulties in identifying and hiring qualified civil engineers. International cooperation partners currently provide engineering expertise in Biogas & DEWATS construction, but contacts with national sector institutions are sustained and enforced to achieve knowledge transfer on a long term.

- Ownership: When a Biogas/DEWAT system has been sponsored by a third party and not – at least in a significant part – been financed by the system owner himself/herself, lack of responsibility and ownership often leads to system performance problems. This could also be observed in cases of community-based systems. TED therefore developed a user training principle that includes not only the technically responsible person but also the person who will benefit most from a well-functioning Biogas/DEWATS – like the cook in a school or orphanage.
- Increasing demand: Increasing demand could only be answered by an increasing number of Biogas/DEWATS constructions; therefore, TED applied for funds from a private donor foundation to train masons, who became part of the TED construction team after an intensive on-the-job training.

Future Directions

Nowadays the highest degree of market maturity of low-tech biogas technology can be found in the area of housing wastewater in decentralized wastewater treatment systems (biogas sanitation or DEWATS), organic sludge treatment, agro-industrial wastewater pretreatment, and treatment of livestock manure. The use of the biogas technology in housing (municipal) wastewater treatment is currently experiencing a rapid increase in Chinese and Indian suburban development. Household biogas plants in developing countries are today usually promoted on a large scale in connection with rural cooking energy supply and environmental issues, and are installed particularly where water pollution through liquid manure from land area unbalanced livestock activities – small, medium, and large – is most severe.

The increasing emission of greenhouse gases, increasing water pollution, declining soil fertility, unsatisfactory

waste management, and the promotion of sustainable renewable energy supply must be seen as parts of the driving factors for biogas technology as one of the important hardware components in a chain of measures to counteract the mentioned challenges.

Due to the fact that often trained constructors leave to search non-rural income in cities and processing industries, the development of prefabricated (composite or membrane) low-tech biogas plant elements will dominate the future constructions. Maintenance issues and responsibilities will be settled by rural plumbers as water and gas supply infrastructure accompanies rural housing development processes. Highly efficient end-energy use appliances for biogas, developed and produced from specialized industries, as already could be learned from China, are contributing to farmers' kitchen hygiene as well as social status upgrading of rural households. Centralized biogas plants will dominate the technology development in densely populated areas as waste-to-energy treatment plants. They could deliver cooking gas for surrounding households, provide electricity and heat for living areas, and cold for dairy farms milk cooling chains.

Glossary

Bioenergy Energy from Biomass [1].

Biogas Gas originating from fermentation [2].

Biogas substrate Biomass that can be used for fermentation processes and which mainly are wet energy crops or residues.

Biomass Material from biological origin excluding material embedded in geological formations and transformed to fossil [1].

Biomethane Upgraded biogas generated through the removal of carbon dioxide.

Biomass residues Biomass originating from side-streams from agricultural, forestry, and industrial operations [1].

Black liquor Liquor obtained from wood during the process of pulp production, the energy content is mainly originating from the content of lignin removed from the wood in the pulping process [1].

Chemical oxygen demand (COD) Amount of oxygen needed for the complete oxidation of the compounds included in the water [4].

Contamination Impurities resulting from exposure to or addition of a poisonous or polluting substance to a fuel [1].

Economic biomass potential Fraction of the technical potential that can be used economically in the context of the economic framework [4].

Energy crops Woody or herbaceous crops grown specifically for their fuel value [1].

Fruit biomass Biomass from the parts of a plant which holds seeds [1].

Fuel Energy carrier intended for energy conversion that can be solid, liquid, or gaseous [1].

Herbaceous biomass Biomass from plants that has no woody stem and which dies back at the end of the growing season [1].

Horticultural residues Biomass residues originating from production, harvesting, and processing in horticulture, including greenhouses [1].

Landscape management residues Residues of woody, herbaceous, and fruit biomass originating from landscape, park, and cemetery management [1].

Realizable biomass potential Expected use of biomass for energy purposes that mainly is part of the economic potential, but can as well be greater is, the option of using bioenergy is subsidized [4].

Segregated biomass Landscape management residues.

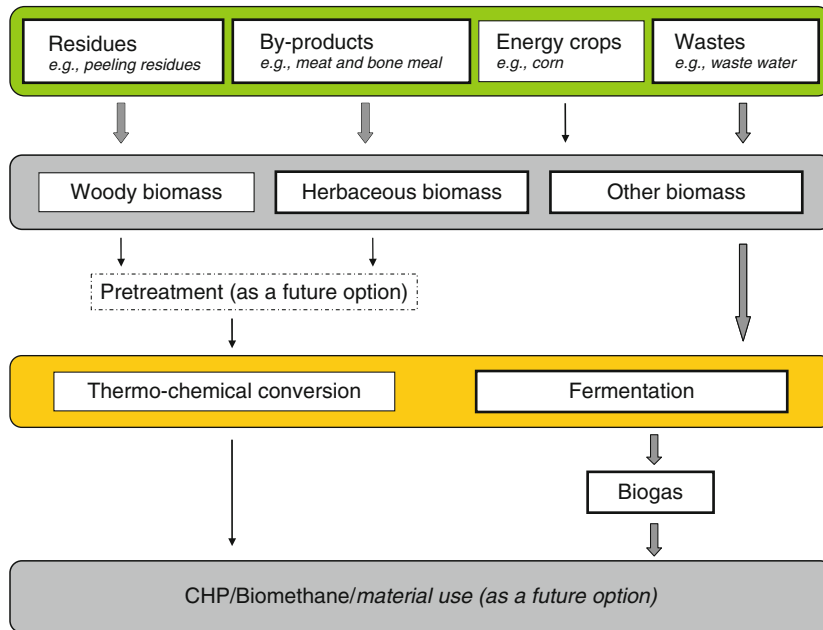

Sludge Sludge formed in the aeration basin during biological waste water treatment or biological treatment process and separated by sedimentation or flotation [1].

Technical biomass potential Part of the theoretical biomass potential which can be used for energy purposes given technical as well as structural and environmental restrictions, including priority for food and fodder production and material uses of biomass [4].

Theoretical biomass potential Theoretical limit of the available energy supply from biomass in a defined area [4].

Definition of the Subject

The production of biomethane can be done following two pathways as shown in Fig. 1. The established one is the anaerobic digestion of wet biomass and the adjacent upgrade of the resulting gas. The second one is based on the thermochemical treatment of solid (dry) biomass as wood. This article focuses on the anaerobic fermentation using residues from municipalities and industrial processes. This process in general includes the degradation of organic matter to acetic acid and other short-chain hydrocarbons as well as the conversion to CH₄, CO₂, and H₂O in an anaerobic milieu.

Biogas Substrates from Municipalities and Industries. Figure 1
Different categories of biomass and possible energetic uses

Suitable substrates have to show the following characteristics:

- Fermentative degradability
- Availability in aqueous milieu

The generation of biogas using anaerobic processes is possible for the conversion of wet organic biomass with little lignin content and organically polluted waste waters [4].

The term potential can be categorized as follows:

- The theoretical potential refers to a theoretical limit of the available energy supply from biomass meaning all phytomass and zoomass. Due to technical, economic, environmental, structural, and administrative restrictions, only a small part of the theoretical potential is available for energy uses.
- The technical potential describes the part of the theoretical potential that can be used given current technical possibilities. The calculation of the technical potential considers available utilization technologies and their efficiency as well as structural, environmental (such as nature conservation areas), and other nontechnical restrictions.

- The economic potential refers to the fraction of the technical potential that can be used economically in the context of the given economic framework. The economic potential is affected, for example, by the development of conventional energy systems and prices of energy sources.
- The realizable potential depicts the expected current use of bioenergy. Usually, it is lower than the economic potential, but can also be greater if, for example, the option of using bioenergy is subsidized in the framework of a market introduction programme [4].

The explanations of biomass potentials for the different categories of residues within this paper refer to the technical potential. Furthermore, the focus is put on biomass fractions which are currently available.

Introduction

Residues, by-products, and wastes are organic materials (biomass) which are generated next to the production of other goods and are suitable for an energy use. These biomass fractions could result from agriculture,

Biogas Substrates from Municipalities and Industries.

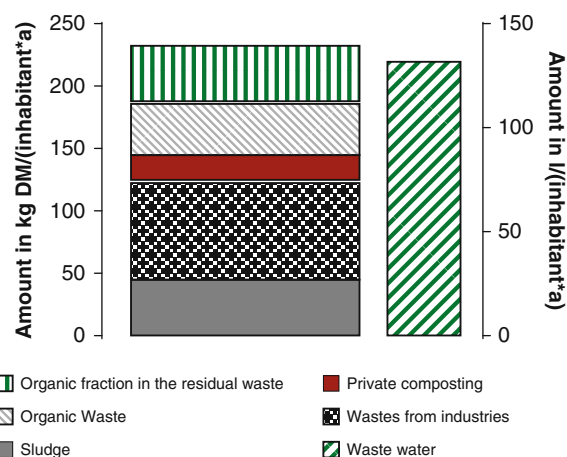

Figure 2

Bandwidth of area-specific amounts of selected residues, by-products, and wastes in Germany

forestry, as well as industry. Furthermore wastes from municipalities with high contents of organic matter are included [2]. This kind of biomass can arise generally during the whole provision chain from supply, production, and use up to the disposal of the organic material.

Residues generally arise depending on area or population, as well as production capacities. Therefore the generated amounts are very heterogeneous based on different factors as climate, type of cultivation, gross national product, and wastes. Especially the amount and composition of industrial wastes vary to a great extent since manufacturing processes have a huge influence regarding the residues and wastes.

Figure 2 shows area-specific amounts of some residues, by-products, and wastes typical for Germany to illustrate the diversity and partially considerable differences of such mass flows. Additionally, Fig. 3 shows examples of generated amounts of significant organic mass flows depending on the population which could be used energetically. According to that especially organic wastes, particularly from industrial processes, provide a substantial population-specific potential.

Biogas Substrates from Municipalities and Industries.

Figure 3

Average specific amount of selected organic residues, by-products, and wastes from households and industry, exemplarily for Germany (2003); the amount can differ regionally; the amounts of manure and organically polluted waste water are not included

Regarding this background, the intention of the following explanations is the presentation of different organic by-products, wastes, and residues from municipalities and industrial processes.

Biogas Substrates from Municipalities

Organic biomass resulting from municipalities can be herbaceous biomass from landscape management measures as well as waste and sludge from households. Some of these materials can be used for the production of biogas. Below these residues and wastes are characterized and their worldwide potential determined.

Landscape Management Residues

Segregated herbaceous biomass results from management measures in gardens, parks, cemeteries, and roads. They accumulate in varying amounts. The herbaceous biomass can be used as biogas substrate.

Herbaceous biomass can result from management measures beside roads. But some of the material stays next to the road because the collection is intensive in labor and costs and thus not realized. In Germany, for example, a collection rate of around 50% can be assumed. The collected material can be composted or

used for energy purposes, for example, as combustion fuel or biogas substrate. But considering the problems regarding the material collection, it does not seem very probable that herbaceous biomass from roadsides will be used for energy generation and especially as biogas substrate in a significant amount. Furthermore, in some countries, there are some limitations resulting from contaminant loads in the biomass.

Herbaceous biomass also arises in parks and cemeteries. The varying area-related amount of the biomass results from different management concepts (e.g., mowing once or more times per annum), and therefore clear and general statements about the available biomass are difficult to make. As an average value 20 t/ha of fresh biomass per annum can be assumed. Furthermore, the composition of this material is quite inhomogeneous and alternates in a huge range. In cemeteries, the amount of flowers, branches, etc., has to be added which cannot be quantified generally. The accumulated biomass often shows a high water content and isn't adapted to an energetic use. Also, some of the material stays on the area which helps closing the nutrition cycle. The rest of the biomass is collected and in most cases still composted although a use for energy purposes is possible. The fresh material can be used as biogas substrate or as solid fuel if it is dried in advance. But both applications are still an exception. Only in waste incineration plants a thermal utilization of the material is realized at the moment to certain extend.

Municipal Waste

Regarding the definition of the Intergovernmental Panel on Climate Change (IPPC) municipal waste includes all wastes collected in municipalities and/or other local authorities. Typically, it comprises household waste, commercial/institutional waste, as well as garden and park waste, and therefore organic compounds and used wood [1]. Below the potential and characteristics of the organic part of the municipal waste will be discussed since this can be used in biogas plants.

Because of its low dry mass content of around 40%, organic waste is particularly suitable as biogas substrate and not as a fuel for a thermochemical conversion [1]. Therefore anaerobic fermentation is used especially in Central Europe, but develops as well in other regions. But this is also a promising option for rural areas in

Asia [3]. Competing uses of the organic waste as material uses don't arise because the digested residue can be used as fertilizer following an aerobic treatment (composting) [4].

The amount of the municipal waste depends more or less directly on the population. The huge amounts of organic waste accumulate in countries with a huge population as China and the USA. In the USA, the generation rate of municipal solid waste is around 1.14 t/cap/year and therefore the highest rate worldwide (Fig. 4). In China, this generation rate is only around 0.27 t/cap/year. Approximately 40% of the waste materials are of organic origin. Also the state of the industrialization is an important factor. The more advanced the industrialization process the more municipal waste is produced.

At present, the organic waste is not separated from the rest of the municipal waste in most cases. This is a huge obstacle regarding the energetic use as a biogas substrate. A separation is common only in Central Europe, but here as well some impurities as plastics cannot be avoided [2].

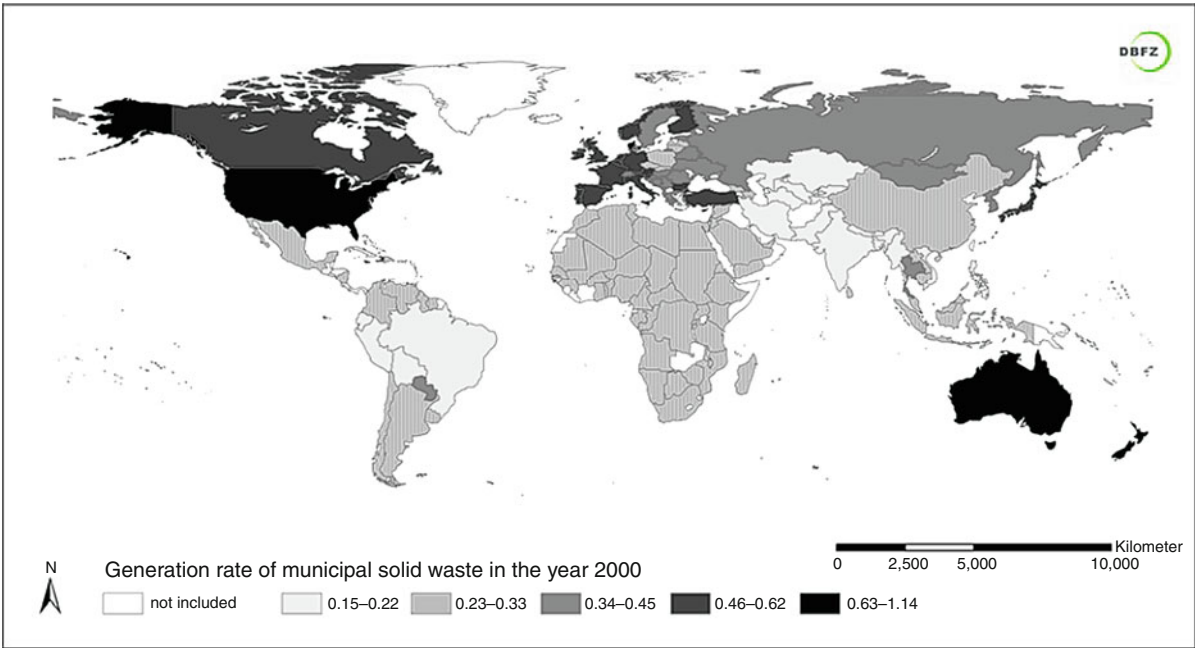

With regard to the access to the substrates, a general collection rate of 75% can be reached in the medium term if the efforts are intensified accordingly.

This leads to a technical potential of 1,160 PJ from organic waste in 134 countries which correspond to around 94% of the world population. The highest potential offers Asia with more than 500 PJ (Fig. 5).

Sludge/Organically Polluted Waste Water from Municipalities

Sludge and organically polluted waste water result from domestic and industrial waste water treatment processes [1]. Aerobic and anaerobic processes can be used for the treatment of these waters. The aerobic treatment is much more common and has a long tradition. However, a huge disadvantage is the high amount of energy needed during the process as well as the great deal of sludge resulting of the treatment. Anaerobic processes on the other hand need more strongly defined conditions and are advantageous especially with a huge part of organic compounds.

Waste waters from municipalities result from households, municipal facilities (schools, hospitalities), and small companies (laundries, restaurants).

Biogas Substrates from Municipalities and Industries. Figure 4
Specific waste production rate in different regions and countries

Biogas Substrates from Municipalities and Industries. Figure 5
Technical potential of municipal waste in different regions in the world

Table 1 shows typical amounts of wastes in the waters exemplarily for Germany. Sewage from municipalities is characterized by variable amounts of pollutants. Roughly one half of these pollutants are of mineral origin (e.g., sand, ash) and organic compounds (e.g.,

excrements, food residues). The waste water is characterized by variations regarding the arising amounts, the composition and the degree of pollution during the seasons and the day. A minimum of the waste water amount is typical in the morning and in winter and a maximum at noon.

Municipal waste water treatment plants separate organic material using a preceding mechanical treatment. Thereafter the waste water is cleaned with aerobic microorganisms which results in a surplus sludge consisting of these microorganisms. Together with the organic sludge from the mechanical treatment, it is fermented in an anaerobic process within a digester. During this process, sewage gas develops which can be used for energy purposes. At first, not the generation of energy but the stabilization of the sludge has been the priority of this specific treatment. But until now, the digesters are also connected to a combined heat and power plant (CHP) to use the energy content of the sewage gas and to contribute to the energy supply of the waste water treatment plant. The quantity of sewage gas averages adds up to around 0.52 m³/kg organic dry substance in the sludge. The composition of the sewage gas is very similar to biogas. In the past, a huge part of

the sludge was used in agriculture and horticulture. Due to more strict limits for selected trace elements more and more sewage sludge is co-fired together with coal in coal fired power plants [2].

Biogas Substrates from Municipalities and Industries.

Table 1 Average pollution of municipal waste water exemplarily for Germany [2]

	Mineral compounds	Organic compounds	Sum
	in g/(inhabitant*day) or in g/m ³ (in parentheses)		
Sediments	20 (100)	30 (150)	50 (250)
Suspended compounds	5 (25)	10 (50)	15 (75)
Dissolved compounds	75 (375)	50 (250)	125 (625)
Sum	100 (500)	90 (450)	190 (950)

Biogas Substrates from Industries

Industrial wastes are those products of a production process that are not reused or recycled and arise next to the production of the primary product. Furthermore, by-products can accumulate during the production. Rather than being waste, these biomass can be reprocessed and used for various material and energy purposes. The residues which amount to significant quantities all over the world can be, for example, residues from the food production industry and from the pulp production or waste paper treatment. [Table 2](#) shows the most important categories of potential biogas substrates generated in the industrial production processes, including characteristic values [2].

The organic residues from industrial processes are often characterized by high water contents and huge loads of nutrients. Therefore a large part of the residues is used for animal feeding and is not (or only in restricted amounts) available for energy purposes. In the course of the industrial processes, a lot of waste water accumulates which could be used for energy generation through anaerobic fermentation [2].

Biogas Substrates from Municipalities and Industries. Table 2 Residues resulting from collected industry segments [2]

Industry segment	Substrate	Typical production specific amounts of waste	Typical organic dry matter content
Cereal manufacturing	Bran, husks, pastry residues	0.2–0.3 kg/kg cereals	85–97%
Manufacturing of fruits, vegetables, and potatoes	Peeling and cleaning residues	0.1–0.35 kg/kg feedstock	20–60%
Sugar production	Chips, molasses	0.7 kg/kg sugar	35–85%
Vegetable oil production	Press cake	1–3 kg/l vegetable oil	80–85%
Beer production	Draff, barm	0.25 kg/l beer	12–25%
Wine production	Marc	0.2–0.3 kg/l wine	30–55%
Alcohol production (distilleries)	Mash	1–3 kg/l ethanol	5–9%
Milk treatment	Whey, mixed with washing water	1–2 kg/l cow milk	5–7%
Meat processing/butchery	Rumen content, meat and bone meal, animal fat	15–60 kg/animal	8–98%
Pulp production	Black liquor	2–3 kg/kg pulp	35–50%
Waste paper treatment	Sludge	0.1–0.3 kg/kg waste paper	40–55%

The specific industrial residues listed in Table 2 will be outlined in the following. Additionally, organic wastes result as well, for example, from the processing of tea and coffee, the production of natural fiber and textiles, the manufacturing of leather, and some further industry sectors [2].

The following numbers given in the text below are valid mostly only for industrialized countries. Furthermore, they can vary significantly in particular cases.

Residues from Cereal Processing

Before cereals can be processed in the baking industry, they have to be ground in mills. There, residues as bran and hulks accumulate which amounts to around 20% of the delivered cereals. Ninety percent of the residues are bran which is used as fodder today. The husks that accumulate additionally during the process can be used as biogas substrate or combustion fuel but could also be composted. Additionally to these residues a certain amount of cereals can be used energetically because of an infection with mycotoxins caused by the weather. These infected cereals cannot be used for the food production any more. These organic residues have to be incinerated.

During the processing of the meal in the baking industry, pastry residues accumulate amounting to 10% of the produced pastries. These residues can be used in biogas plants. All residues from the cereal production show a huge amount of dry matter. Waste waters arise to a small degree regarding to washing and peeling processes [5]. The highest amounts of residues

from cereal production can be expected in Asia where most cereals are produced (Table 3).

Residues from the Manufacturing of Fruits, Vegetables, and Potatoes

This group of residues contains quite a lot of producers and products (e.g., fruit juice, vinegar, dry fruits). The fruits, vegetables, and potatoes are mostly of agricultural origin and are processed in bigger companies of the food industry. Different organic residues and wastes as peeling residues, washing waters of fruits, and pressed out fruits can accumulate during the treatment. Further possible residues are filtration residues, draff, and marc from the distillation of fermented fruits, potato peels, concentrates, returned goods, and more. Depending on the production process, different amounts of residues (10–30% of the fruits, vegetables, and potatoes) can arise. These materials can be fermented, composted, burned, or used in other ways as the production of alcohol, soups, pectin, aroma, and cosmetics. Furthermore, organic polluted waste waters can accumulate amounting to 1–3 m³/t of the product which could be used in the farm animal keeping [2].

Residues from fruit originate from the production from fruit juices and derived products. Due to an increasing popularity of these products, the amounts of the residues rise as well. The most important fruits are citrus fruits, apples, and grapes. Around 27 mn t of the citrus production are processed to juice, essential oils, and other products which leaves around 50% of the fresh fruit weight as a by-product. The world apple production comprises approximately 54.2 mn t of apples whereof China alone produces 25 mn t. Apples which are not suitable for consumption generate large amounts of residues which can be processed. In total, around 14 mn t of apples are processed for the production of juice, pulp, and jelly (Table 4). Apple pomace results from the fruit pressing and represents up to 30% of the fresh fruit. Grapes can be processed to wine, juice, jams, and raisins. In total, 58 mn t are produced annually especially in Italy (16%), France (12%), the USA (11%), and Spain (10%). Eighty percent of these fruits are used for wine making, and as a by-product from the production, grape pomace results in an estimated amount of 13% of the original fruit.

Biogas Substrates from Municipalities and Industries.

Table 3 Total cereal production in different regions worldwide [6]

	Total cereal production (t)
Asia	1,188,100,000
Africa	151,370,000
Oceania	34,560,000
Europe	504,365,000
America	646,710,000

Biogas Substrates from Municipalities and Industries.**Table 4** Amounts of processed citrus, apples, and grapes worldwide per annum and resulting by-products, respectively, residues

	Processed amount (mn t/a)	By-products/residues (%)	By-products/residues (mn t/a)
Citrus	27	50	13.5
Apples	14	30	4.2
Grapes	46.4 wine	13	6

Residues from Sugar Production

Sugar can be produced from sugar-beet or from sugarcane. The production of sugar based on sugar-beet generates crystal sugar amounting to around 17% of the original weight of the beet. The residues are wastes from sugar-beet (around 1.5 kg/kg of sugar), pulp, and molasses (0.24 kg/kg sugar). Currently, these mass streams are used for the production of syrup and yeast and as fodder. Additionally, huge amounts of organically polluted waste waters result, for example, from the washing of the sugar-beet and the chemical extraction of crude sugar. These waters however are recycled and used in the process water cycle.

Residues from Vegetable Oil Production

Additionally huge amounts of residues, wastes, and by-products result from the production of vegetable oils. The production of 1 l rapeseed oil, for example, leads to 1.4 kg rapeseed cake or rapeseed meal. These by-products are often used as fodder for animal breeding. If the rising demand for oil as fuel leads to higher amounts of residues, the additional rapeseed cakes and rapeseed meals could be used for energy purposes. Especially the use as combustion fuel seems promising. Furthermore, the glycerine from the process of transesterification could be an interesting residue.

Residues from Beer Production

The manufacture of beer involves the generation of some typical by-products and residues which are

Biogas Substrates from Municipalities and Industries.**Table 5** Residues from the production of 100 l of beer

	Residue per 100 l of produced beer
Spent grains	2,000 g
Spent hop	100–300 g
Surplus yeast	?

spent grains, hops, and surplus yeast. These result from the processing of the raw materials and are available in huge amounts because the use is still limited. Therefore the residues represent large potentials for various uses which would also be a solution to environmental problems which arise with the disposal and land filling of the material.

The by-products from the beer production can accumulate as a residue from the malting at the end of the process and comprise the husks of the malt which are rich of cellulose. Furthermore, it consists of nitrogen and vegetable fats and is therefore used as fodder, for example, in the dairy farming. Other possible uses are in biotechnological processes as fermentation, as substrate for the cultivation of microorganisms, or as raw material for the extraction of proteins, sugars, and acids [7].

Additionally, 2.5–6 l waste water arises from the production of 1 l beer which can be treated in biogas plants together with the other residues [2]. Furthermore, 200 t of spent grains (70–80% water content) are generated with the production of 10 mn l of beer. They are basically composed by barley grain husks. The material is rich in cellulose, hemicellulose, and lignin and has high protein content. The hop is used for the brewing and is rich in components which supply the bitter and aroma components to the beer. However, 85% of the raw material ends up as residues [7]. For the production of 100 l of beer, 100–300 g of hop is needed, and therefore 85–255 g are left as residue (Table 5). The third residue of the brewing process is the surplus yeast. However, it is not easy to state how much of the yeast is left for other uses because it can be used for the next brewing process.

In 2008, the global beer consumption reached 146.2 billion litres which would cause around 365.5–877.2 billion liters of waste waters [6].

Residues from Wine Production

The production of wine is a very important industry in many countries all over the world and generates huge amounts of organic residues such as sugars and cellulose. One of the residues is distilled grape marc which is a complex lignocellulosic material [7]. It is produced after pressing the grapes in white wine processing or after the fermentation and maceration in the red wine production. The production of 100 l of wine generates 25 kg of marc and 200–300 l of waste waters as residues. These are used especially in distilleries or in agriculture as fertilizer or animal feed. As an alternative the fermentation in biogas plants is possible as well [2].

In 2008, the wine production reached around 27,270 million liters [6]. Therefore the amount of residues generated worldwide was about 6,818 million kilogram of marc and 54,540–82,810 million liters of waste waters.

Residues in Distilleries

The fermentative conversion of sugar (e.g., from fruits) and starch (e.g., from cereals) to ethyl alcohol is made in distilleries. This processes of fermentation and distillation generates residues (draff, stillage) which can be used energetically by an anaerobic fermentation. The production of 1 l ethanol from cereals produces around 10–14 l of wet stillage (2–8% of dry substance) which can be concentrated to 0.75 kg of dried distillers grains with soluble (DDGS). The draff can be used as fertilizer on agricultural areas or as animal feed. Thus, distilleries are predominantly in peripheral areas and a use could only be reasonable if the generated energy can be used locally [2].

Residues from Milk Production

Whey is the characteristic by-product of the processing of milk to cheese, curd, and cream cheese. It can be distinguished between sweet whey and acid whey which is generated using lactic acid producing bacteria. Furthermore, waste water accumulates amounting to about 2 m³ per liter milk. With a total milk production of 690 mn l in 2008 [6], this would generate about 1,380 mn l of waste water. Generally these waters are mixed with other solid and fluid residues and reprocessed to whey

powder and drinks or used as fodder for pigs, etc. In some cases, the residues can be fermented in biogas plants [2].

Residues from Meat Processing

Every year, around 50,000 head of cattle, 500,000 pigs, and 28,000 sheep, goats, and horses are slaughtered per one million inhabitants, for example, in Germany. The residues from the slaughtering amount to 30 kg per inhabitant in a year. These can be used for material as well as for energy purposes. Especially since the emergence of BSE meat and bone meals are applied in the chemical industry and for the production of fertilizer. Furthermore, few plants for the generation of methyl ester from animal fats to be used as fuel exist, for example, in Germany. Prospectively, the recycling of phosphate from meat and bone meal could gain in importance [2]. Nevertheless, there is indeed a potential of such residues to be used as a feed for biogas plants.

Residues from Pulp and Paper Production

In the pulp and paper industry, two processes have to be distinguished: the generation of cellulosic pulp and the production of paper and cardboard. The production of cellulose leads to the generation of black liquor. It contains the lignin part of the wood which cannot be utilized for the paper production. Black liquor is already used in most paper plants as a fuel to meet the internal energy demand. Another residue of the pulp and paper production is industrial sludge contaminated with fiber which could account up to 30% of the raw material. These sludge can be dried and combusted as a solid fuel. They can as well be used for material purposes such as amelioration in the agriculture and for the production of bricks. Furthermore, huge amounts of waste waters accumulate during the paper production process – around 10 m³/t paper produced [2]. This waste water can be treated under anaerobic conditions.

Sludge/Organically Polluted Waste Water from Industries

Organically polluted waste waters from industries are characterized by huge variations in the available

Biogas Substrates from Municipalities and Industries. Figure 6

COD – Concentration ranges of waste water from different industrial sectors [4]

amount throughout the course of a day or a year. Variations can as well be observed regarding the degree of contamination which varies especially in sugar refineries, vegetable processing, and distilleries and depending on technical aspects. Internal water circulation, for example, leads to considerable reductions of waste water amounts. On average, 2–3 m³ of industrial waste water accumulate per inhabitant and year in Germany. Typical contaminations are around 1,000 and 100,000 g COD/l (COD describes the amount of oxygen needed to oxidize all ingredients completely; Fig. 6). Industrial sludge account to up to 10 kg_{DM} per inhabitant and year, for example, in Germany, and is used for energy purposes almost completely [2].

Future Directions

Residues from industrial processes and municipalities are diverse and offer various possibilities for material and energy. Furthermore, residues offer huge potentials for the production of biogas, although it is difficult to quantify the potentials of all residues and by-products worldwide since statistical data are not available in many cases. Additionally, a part of the biomass is already in use. They can be used for material purposes or for feed and fodder such as rapeseed cakes. Other materials are already in use for energy purposes such as black liquor which

covers parts of the internal energy demand of paper production plants.

The future trends regarding the amount and availability of municipal and industrial residues and by-products for the biogas production depend on the development of the population, the progress of the industrialization process, and development of the specific industries. Furthermore, competitive uses have to be considered.

Glossary

Stress Any change(s) in physiology and biochemical process that causes deviation from a normal state of an organism and requires an adjustment to return to the normal state.

Stressor An agent, condition, or other stimulus that causes stress.

Biomarker A biological chemical or macromolecule used as an indicator of a biological state that is often reflected by changes in its concentration.

Toxicity Degree of poisoning or damage caused by a substance to an exposed organism.

Metabolome The whole set of metabolites, forming an extensive network of metabolic reactions, in a biological system (e.g., an organism, organ, or cell).

Metabolomics Comprehensive study of a metabolome or a set of metabolites in which one metabolite from a specific pathway affects one or more biochemical reactions, or a comprehensive and quantitative analysis of all metabolites.

Omics Comprehensive study of a biological system. Omics fields include genomics, proteomics, metabolomics, and transcriptomics.

Definition of the Subject

To evaluate the biological effect(s) of a stress, it is necessary to identify and characterize the stressor (s). In general, stressors can be classified as toxicants, pathogens, and physical stimulants. Although the reactions and the degree of response may vary, stressors frequently induce extensive metabolic changes in a living organism. Comparative research on a large set of metabolites at different stress states can provide detailed insights into specific biochemical reactions and metabolic networks. Such information can be used for diagnosis of a disease or toxic effect, development of therapeutic remedies to relieve the stress or its detrimental effect, etc.

The rapid accumulation of genomic and proteomic information of various organisms and rapid advancement in analytical capability make new disciplines of omics possible. In comparison with conventional approaches that usually focus on specific biochemical pathways, a major interest of omics is to gain system-wide information about the target organism and biochemical events. The main goal of metabolomics is qualitative and quantitative differentiation of an entire set of metabolites and the biological networks in the target organism [1, 2]. Metabolite profiles, fingerprints, and related concepts have been applied in various biochemical and toxicological studies since the 1980s [3, 4]. Metabolomics is an emerging discipline and has been shown to be a powerful tool for biomarker discovery and stress research. A related term, metabonomics has also been widely used in the

literature. In this chapter, both metabolomics and metabonomics are regarded as having the same meaning. This chapter discusses the metabolomics of animals, plants, and microorganisms relevant to environmental toxicology.

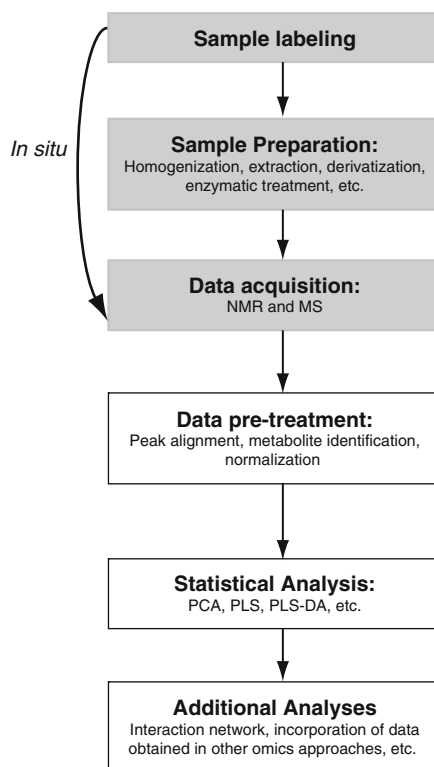

Introduction

Biomarkers provide direct evidence of stress or potential stress. There are different types of biomarkers. Some biomarkers indicate different stages of disease: early threat (i.e., risk indicator or predictive biomarkers), existence (i.e., diagnostic biomarker), and disease development (i.e., prognostic biomarker). Some biomarkers give an indication of chemical toxicity, while others indicate physical stresses. It is widely known that cholesterol values are a biomarker indicating coronary and vascular disease risks. Molecular biomarkers need to be naturally stable for chemical analysis, to be reliably quantified, and to be effective for diagnosis, prognosis, and risk assessment. In environmental toxicology, biomarkers play a major role in environmental risk assessment, exposure, and management. Biomarker-based biological monitoring aids in early risk diagnosis, risk prevention and minimization, action target identification, toxic response, bioremediation, etc. The analytical method for a biomarker must be accurate, simple, reproducible, and cost-effective. Many genomics, metabolomics, and proteomics techniques are available for biomarker discovery. It is noteworthy that discovery of a biomarker typically requires a large amount of research effort. Biomarkers can be difficult to validate and may require different levels of validation.

Metabolomics has been largely employed to analyze all metabolites (i.e., global analysis) in a biological sample. Metabolomics experiments typically involve sampling, sample preparation, extraction, fractionation, detection, measurement, and data mining and management. Although metabolomics concerns the entirety of metabolites as analytical targets, it is practically impossible to cover all with a single analytical method. A large portion of metabolites are water-soluble, whereas steroids and respiratory quinones, for example, are practically water insoluble. It is well recognized that metabolomic responses are more rapid than other omics targets upon a stimulus. Hence,

cautious and rapid handling of samples is very important to preserve the integrity of the metabolome. Common sample preparation protocols include proper labeling and storage of biological specimens, homogenization, extraction, cleanup, and concentration (Fig. 1). Additional procedures are often used to enhance the data quality and instrument performance, including enzymatic treatment to remove proteins and excess metabolites. In a metabolomics study targeting a specific set of metabolites, specialized enrichment techniques are often utilized [5, 6].

Instrumental analyses are an integral step in metabolomics research. Metabolomics methodologies can be divided into chemical separations and measurements. Instrumentation commonly used in metabolomics includes nuclear magnetic resonance

Biomarkers and Metabolomics, Evidence of Stress.

Figure 1

A common metabolomics workflow. PCA, principal component analysis; PLS, partial least squares; DA, discriminant analysis

spectroscopy (NMR) and mass spectrometry (MS). MS is widely used in metabolomics because it can provide rapid and sensitive qualitative and quantitative analyses of metabolites [7, 8]. High selectivity and sensitivity can be achieved by using tandem mass spectrometer systems where a mass spectrometer is hyphenated with another mass spectrometer and/or coupled with a separation technique. Some mass spectrometers such as Fourier Transformation cyclotron resonance MS (FT-ICR MS) have enough resolution power, eliminating chromatographic or electrophoretic separation requirements [9–11]. NMR has been applied in metabolomics since the 1980s [4]. Its strengths include rapid data acquisition with minimal sample preparation time, high reproducibility, and rich structural information. These factors make NMR among the most popular tools for high throughput applications. Disadvantages in comparison with gas chromatography-MS (GC-MS) include low sensitivity and less comprehensive spectral libraries. Data from instrumental analysis require comprehensive interpretation, often accompanied by pretreatment of data (e.g., spectral deconvolution, peak alignment, and structural identification of specific metabolites).

A single metabolomics experiment can generate huge amounts of data leading to a comprehensive understanding of metabolic networks, whereas conventional approaches deal with a limited number of biochemical reactions. Complementary information from proteomics and genomics is often incorporated into a metabolomics data set to further interpretation of the biological events. Sophisticated statistical procedures are often necessary to uncover data of biological significance. Several data reduction methods, including principal component analysis (PCA), discriminant analysis (DA), partial least squares (PLS), and other newly introduced methods (e.g., Support Vector Machine and Neural Network) are used [12–15].

Integrated omics approaches are increasingly being used to verify and visualize metabolic differentiations. For example, Okuda et al. [16] reported the potential utility of the KEGG (Kyoto Encyclopedia of Genes and Genomes) atlas for global analysis of metabolic pathways and metabolomics. Many excellent reviews of metabolomics are available [17–22].

Applications of Metabolomics

Metabolomics in Animal Sciences

Metabolomics is considered to be the most promising omics tool for system-wide evaluation of stressors because primary metabolites are well conserved throughout the phylogenetic kingdoms [23, 24]. Chemical, physical, and biological stimuli have been studied. Much of the current research deals with mammals challenged by diseases, toxicants, and pathogens. Applications in this field are centered on the discovery of biomarkers for specific stressors, as exemplified in Table 1. Furthermore, metabolomics can provide insights into mechanisms of stress response, which can assist in the development of proper treatment methods [25, 26].

Mammalian metabolomes are more complex than those of plants and microorganisms. The concentrations of different metabolites in the same sample vary dramatically. In addition, both the concentrations and chemical identities of metabolites vary largely among different organs, sexes, ages, physiological stages, and numerous other factors. One of the most noticeable recent advancements was the construction of a metabolite database [27]. The human metabolome database (HMDB) is a comprehensive data resource of metabolites found in the human body (<http://www.hmdb.ca>). Many toxicological studies via metabolomics are approached with metabolic fingerprinting and pattern recognition where knowing the exact identities of metabolites is not a prerequisite. Such applications of metabolomics have been used in clinical diagnostics. Biofluids such as blood and urine are commonly used samples. Figure 2 shows several common marker metabolites regardless of the stressor types (i.e., non-stress-specific biomarkers) [28–30]. In environmental toxicology, this type of biomarker can be used for the first tier of monitoring. The use of organic acids and creatine as biomarkers is often criticized due to their lack of stress specificity. It is noteworthy that the data from metabolomics should be interpreted on the basis of pattern changes rather than simple concentration changes of a few metabolites. The simple fingerprints along with structural identification can give comprehensive and detailed information of cellular status. Metabolomic profiles and structural analyses, for

**Biomarkers and Metabolomics, Evidence of Stress. Figure 2**

Structures of selected biomarkers in stressed animals, plants, or microorganisms

example, delineated a potential role for sarcosine in prostate cancer progression [31].

In drug discovery, many steps of evaluation are required, including screening for intended bioactivity (potency), adverse effects (toxicity), dose–

response (efficacy), and metabolism (detoxification). Metabolic modulation of xenobiotics (drugs and pesticides) can trigger complicated problems because the extensive structural modification of xenobiotics through metabolism can alter the

potency or toxicological profiles of the parent compounds. Holistic approaches, like metabolomics, may be a useful solution for drug discovery [32]. Metabolomic investigation of mode of action has been used to identify the exact targets and metabolic pathways of preclinical drugs. Watson et al. [33] identified the mode of action of an anticancer drug through global metabolic profiling. The mode of action of complex molecules (e.g., peptides and proteins) has been assessed with metabolomics. Angiotensin II (a well-known hormone) induces mitochondrial dysfunction. Mervaala et al. [34] used metabolomic methods to study the influence of angiotensin II on the metabolic profile and determine the mode of action of angiotensin II. They found that distinct patterns of cardiac substrate use in angiotensin II-induced cardiac hypertrophy are associated with mitochondrial dysfunction. In addition to natural primary metabolites, drug metabolites are profiled to obtain comprehensive data. The recent studies with naphthoquinone derivatives revealed that the toxicity of these chemicals is due to redox impairment, which causes strong oxidative stress [35]. It was found that oxidative stresses in response to acetaminophen in rats include depletion of antioxidants (e.g., ferulic acid), trigonelline, S-adenosyl-L-methionine, and energy-related metabolites [36, 37].

Pesticides are the cornerstones of pest management, food security, and public health. There are, however, public concerns about potential adverse effects of pesticides. Metabolomic evaluations of pesticide toxicity are much fewer than those of human drugs and diseases [38]. Similarly, a limited number of publications are available concerning metabolomics with organic pollutants. However, related research has gained some attention from scientific communities and regulatory organizations. Earlier studies of *in vivo* pesticide evaluation have indicated the complexity of the issue, particularly in higher animals. A specific pesticide can yield many metabolites with different toxicities [39–41]. In general, recently registered pesticides have much improved performance, including higher target selectivity, shorter half-lives, and fewer side effects (e.g., toxicity to nontarget organisms). In spite of these improvements, side effects are inevitable. Acetylcholine esterase is the target enzyme of organophosphorus insecticides (OPs). Some OPs are potent inhibitors of

cytochrome P450 (CYP), a key enzyme of xenobiotic detoxification [42]. Azole fungicides target the fungal sterol 14[α]-demethylase used in ergosterol biosynthesis, but some of them can also inhibit mammalian sterol 14[α]-demethylase. Ekman et al. [43] analyzed metabolomic differences between normal and triazole fungicide-treated rats. The differential accumulation and depletion of some marker metabolites (creatine, choline, some osmolytes, and branched amino acids) in a dose-dependent manner were observed. Distinguishable metabolomic patterns indicated chemical-specific stresses of these fungicides [43, 44].

Mammalian metabolomics in response to heavy metals are frequently reported. Several heavy metals such as arsenic, cadmium, and mercury are commonly known environmental contaminants, especially in mining areas. Mally et al. [45] reported that 4-hydroxy-2(E)-nonenal is a potential biomarker of toxic mineral exposure, and its accumulation possibly indicates heavy metal-induced renal failure. Metabolomic analyses in the sera of cinnabar (mercury sulfide)-treated rats showed elevated concentrations of ketone bodies (3-D-hydroxybutyrate and acetoacetate), branched amino acids, choline, and creatine and decreased concentrations of glucose, lipids, and lipoproteins [46]. Similar metabolic profiles were also found in rats in response to realgar (arsenic sulfide) [47]. Accumulation of creatine, betaine, and some nitrogen-containing metabolites was the common, characteristic response to arsenic and mercury. The levels of glutathione and *N*-acyl amino acids, however, varied depending upon heavy metals and tissues [46, 47]. Toxicities of nano-materials are an emerging issue. Nano copper particles induced extensive changes of rat metabolomes [48]. An increase in triglycerides in the serum, liver, and kidney tissues could serve as a potentially sensitive biomarker for nano copper-induced lipidosis.

Target analytes in most metabolomics are naturally produced metabolites. However, recent studies of drug metabolism in conjunction with profiling natural metabolites suggested and confirmed novel toxicity biomarkers and toxicity mechanisms [49–52]. These studies produced extensive metabolic profiles of specific chemical stressors (e.g., drugs, pesticides, or environmental contaminants). Because the potency or toxicity of metabolites may differ from the parent

chemicals, comprehensive profiling of metabolites can offer valuable information to evaluate chemical toxicity. Chen et al. [51] profiled both natural and drug metabolites and identified conjugates of acetaminophen metabolites as promising biomarkers of acetaminophen-induced toxicity. In addition, the oxidative stress elicited by CYP2E1-mediated acetaminophen metabolism might significantly contribute to its toxicity.

Recent studies have indicated several interesting aspects of nutritional metabolomics. Synergistic effects of co-application of anticancer drugs and methionine deprivation are well known for treatment of some cancers. However, the exact mechanism was not well understood. Guenin et al. [53] found that methionine deprivation affects several metabolite pools, including phospholipid and S-adenosyl-methionine. Changes of these metabolites are accompanied with abnormal expression of some proteins and other key metabolites involved in tumor proliferation. Colon cancer is associated with diet, including higher intake of dietary sugar. Hansen et al. [54] applied metabolomics to investigate the relationships between the incidence of colon cancer and sucrose, glucose, and fructose. These sugars increased mutation rates in the colon and bulky adduct levels in the colon and liver to a similar extent. The metabolomics studies indicated disturbed amino acid metabolism and a decrease in plasma and urinary acetate to be a common feature for all dietary sugars and confirmed triglyceridemic effects of fructose. Accumulation of DNA-adducts was usually accompanied with a decrease of antioxidants, especially methionine. Increased colon cancer with associated changes of metabolic profiles indicated that a high sugar diet may affect the biochemical environment and may increase the probability of cancer development. In comparison with other stress-related metabolomic research, effects of food are often difficult to study, since food is a very complex mixture of chemicals. Routes of absorption, distribution, metabolism, and excretion (ADME) of specific constituents in the tested food can influence metabolic responses. A recent study on human consumption of chocolate has illustrated interesting metabolomic effects and a strong correlation with psychological activity [55]. Decreased excretion (or levels) of cortisol (stress hormone) was the most apparent effect of chocolate in

reducing anxiety. This exemplifies the power of metabolomics to evaluate the effect of complex mixtures.

Animals are frequently exposed to physical stress (temperature, wound, etc.). Teague et al. [56] studied metabolomic responses of rats under physical stresses—namely, shaking the cage occasionally. They found several different marker metabolites, depending upon the shaking duration. As acute response, the accumulation of glucose and ketone bodies was accompanied with the repression of acetate and branched amino acids. Prolonged shaking induced additional metabolomic changes (e.g., increase of choline). A recent study with rats indicated that extensive metabolomic changes can occur during restraint stress [57]. Notable responses included differential levels of metabolites in glycolysis, the tricarboxylic acid (TCA) cycle, fatty acid oxidation, and urea cycles.

Environmental metabolomics, particularly targeting non-model animals, is more difficult because the needed information such as gene sequences and protein databases is limited, and the organisms are usually exposed to multiple stressors [17]. The recent social interests in environmental issues have accelerated such research needs. Metabolomes of various organisms were recently assessed, and fish were the most common model organisms. These species include Chinook salmon (*Onchorhynchus tshawytscha*), flatfish (*Limanda limanda*), fathead minnow (*Pimephales promelas*), and Japanese medaka (*Oryzias latipes*) [43, 58–62]. Although multiple stressors are common in the environment, metabolomic studies with these animals often focus on a specific stimulus (disease or chemical stress). Ekman et al. [58] reported that metabolomic responses to the fungicide vinclozolin in fathead minnows included changes in the concentrations of several metabolites including creatine and betaine. Viant et al. [61] reported that several metabolites, most notably of energy-related intermediates (e.g., ATP), amino acids, and creatine, accumulated in Chinook salmon exposed to the pesticides dinoseb, diazinon, and esfenvalerate. Japanese medaka also gave a similar response to dinoseb [62]. In general, hydrophilic metabolites are more common metabolomics target molecules. Steroidal lipids were also proven to be good marker metabolites in rainbow trout (*Oncorhynchus mykiss*) in response to environmental estrogens [59].

Recent metabolomics studies revealed the effects of pesticides on several invertebrate species such as earthworms (*Eisenia* spp. and *Lumbricus rubellus*) [63–68]. In a multi-platform analysis of earthworm metabolomes, McKelvie et al. [68] found that DDT and endosulfan affected the levels of sugars and amino acids. The comparative analyses suggested the ratio of alanine to glycine as a potential biomarker of pesticide exposure. Rochfort et al. [69] observed a clear indication of different metabolomic patterns in earthworms being relevant to soil health.

Mollusks such as abalones and mussels are usually considered to be relevant marker species of chemical stress in the marine environment. Tuffnail et al. [70] investigated metabolomic responses of blue mussels (*Mytilus edulis*) under various physical and chemical stressors. In this case, alanine and some osmolytes were the important factors to discriminate different stress types. Research with red abalone (*Haliotis rufescens*) also indicated several osmolytes, amino acids, and storage carbohydrates (e.g., glycogen) to be the common indicators of environmental stresses [71]. Metabolomics studies with either freshwater or marine-dwelling crustaceans are quite limited. Recent examples with *Daphnia* and *Diporeia* concerned the metabolomic evaluation of atrazine and heavy metals [11, 72]. Several amino acids and amines were characterized as useful biomarkers through the analysis of metabolomes. However, detailed connections between this information and other biochemical observations are still missing.

Birds are important parts of ecosystems and food resources. However, metabolomic research has been very limited in this subject. Approximately 300 research articles have been published in other omics areas for chickens, but only one metabolomic publication was found as of April, 2010. Huber et al. [73] studied the effects of organically and conventionally produced feeds on a chicken model. Small but noticeable differences of metabolic profiles were observed, which may be correlated with animal productivity. Research is needed to fill in the knowledge gaps of metabolomic responses to stressors in birds.

Metabolomic research has also been very limited in insects, which are important parts of ecosystems. Recent studies with *Drosophila melanogaster* indicated that several metabolites (e.g., glutamate and choline)

give differential responses against hypoxia and heat [74, 75]. Future metabolomics studies with insects are of great significance, particularly for ecosystems, agriculture, and food security.

Applications in Plant Sciences

Plants are fundamental to our life. Much research has been published on practically every aspect of plants. Most applications of metabolomics in plant sciences are phenotyping or simple mapping of metabolites. Many publications of plant metabolomics under various types of stresses have been published [76–79] although fewer than those concerning animals. Table 2 shows common physical, chemical, and biological stressors.

Temporal dynamics of metabolomes in heat and cold-stressed *Arabidopsis thaliana* have been monitored [80]. In general, cold shock influences metabolism far more profoundly than heat shock. However, a large portion of heat- and cold-shock responses overlaps. Those include accumulation of amino acids derived from pyruvate and oxaloacetate, polyamine precursors, and compatible solutes [80]. Rudell et al. [81] studied metabolomic changes of apples in response to cold and suggested that a wide array of metabolomes were changed under the specified conditions. Studies indicated that some antioxidants or plant growth regulators may alleviate the damage of cold stress. Although there were several unique responses, depending on the nature of stressors, physical stimuli usually induced accumulation of oxylipins [82]. Several jasmonate derivatives were identified as useful biomarkers of wound-induced response in *A. thaliana* [83] (Fig. 2).

Heavy metals are common stressors to plants. They are commonly used as toxicant models in metabolomics and other omics research. Plants that are highly tolerable to heavy metals usually produce a large amount of small peptides, called phytochelatins. Metabolic profiling of cadmium-treated *A. thaliana* has shown an accumulation of several phytochelatins [84]. Phytochelatins are oligomers of glutathione containing cysteine, glutamate, and glycine. Metabolomic differentiation in sulfur-containing amino acids is a commonly observed phenomenon in heavy metal-stressed plants, signifying an adaptive response to heavy metals. Other common metabolites indicating

Biomarkers and Metabolomics, Evidence of Stress. Table 2 Examples of plant metabolomic studies under various stressors

Type of study	Plant	Stressor	Description	Reference
Biomarker discovery	<i>Arabidopsis thaliana</i>	Physical (heat, cold)	Accumulation of amino acid and osmolytes	[80]
	<i>A. thaliana</i>	Physical (wound)	Accumulation of oxylipins and jasmonates	[82, 83]
	<i>A. thaliana</i>	Heavy metal (Cd)	Accumulation of phytochelatins and precursors	[84]
	<i>Hordeum vulgare</i> (barley)	Salt stress	Accumulation of proline, sucrose, and glucose	[91]

Mode of action	<i>Zea mays</i> (corn)	Pesticides	Mode of action specific metabolomic response to 24 herbicides	[94]
	<i>Lemna minor</i>	Pesticides	Mode of action-dependent changes of amino acids and precursors	[96]
Toxicity	<i>Oryza sativa</i> (rice)	Ozone	Integrative approaches with metabolomics, transcriptomics, and proteomics	[103]
Biological stress	<i>Brassica rapa</i> (Chinese cabbage)	Insects	Differential accumulation of alanine, threonine, glucose, sucrose, feruloyl malate, sinapoyl malate, and gluconapin	[99]

adaptive changes include sugars and sugar alcohols. Plants can also modulate secondary metabolism in response to heavy metals such as copper and mercury. Jahangir et al. [85] observed an increase in the secondary metabolism and differentiation of amino acid and sugar levels in Chinese cabbage (*Brassica rapa*) when it was treated with copper, iron, and manganese. Rapid accumulation of glucosinolates (a secondary metabolite) was observed in *A. thaliana* under nutritional stresses [86]. These findings indicate that there may be a common feature of stress from exposure to heavy metal and nutrient deficiency.

High soil salinity significantly impacts plant growth and decreases crop yields. Salinity-related stresses are frequently accompanied with low water supplies in agricultural practices. The metabolic impact of salt stress was assessed on several crops and plant models (e.g., *A. thaliana*, barley, grape, rice, and tomato) [78, 87–91]. Accumulations of proline, sucrose/glucose, and inositol are the most frequently observed response

in salt-stressed plants. Another common response includes up-regulation of proteins involved in polyamine and γ -aminobutyric acid metabolism and associated metabolites. The levels of organic acids in the TCA cycle usually decrease under salt stress, which may indicate reduced cellular activity. A general conclusion from metabolomics studies of salt-stressed plants includes changes in organic acid, amino acid and sugar metabolism.

Metabolomic profiles of plants under water stress share a common feature with those under salt stress, including increased sugar content [92]. Plants are primary sources of human foods. Therefore, plant metabolism under different nutritional conditions (i.e., fertilization) is of tremendous importance. However, only a limited number of papers have been published. *A. thaliana* is the most commonly used plant model. Hirai et al. [93] studied metabolite profiles and transcriptomes of *A. thaliana* under sulfur or nitrogen limitation. Several genes and metabolites were

commonly expressed under both sulfur and nitrogen deficiencies. For example, nitrate reductase, a key enzyme of nitrogen assimilation, was down-regulated under both conditions. Reduction of this enzyme and the associated metabolites indicated that reduced metabolic rates may be a common response to nutrient deprivation. However, some metabolites such as glucosinolates were differently accumulated between nitrogen- and sulfur-deficient conditions. Metabolic consequences of sulfur-limitation in plants were further investigated by Nikiforova et al. [86]. Limited supplementation of sulfate leads to a decrease in sulfur metabolite pools (e.g., cysteine and methionine). Because these metabolites are an integral part of plant metabolism, sulfur deficiency induces a number of adaptive responses. Decreases in biomass, levels of proteins, chlorophylls, and total RNA suggest a general reduction of metabolic activity. These responses are compensated by a systemic adjustment of the major metabolic pathways. Representative responses include re-partitioning of sulfur, carbon, and nitrogen through the accumulation of metabolites.

Metabolomic investigations of pesticide effects on plants are limited. Ott et al. [94] studied metabolomic responses in corn (*Zea mays*) treated with 24 different herbicides. They successfully discriminated chemicals having different modes of action. Comparative metabolomic studies with pyrenophorol indicated that this fungal toxin may have different modes of action from the commercial herbicides used on the oat *Avena sterilis* [95]. Recently, the metabolic response of the aquatic weed *Lemna minor* was investigated in relation to herbicidal activities of glyphosate, atrazines, and other chemicals [96]. GC-MS based metabolomics of *A. thaliana* indicated that herbicides having different modes of action result in notably different metabolomes [97]. For example, sulfonylurea herbicides induced large differences in metabolite profiles, specifically those involved in glycolysis, the TCA cycle, and nitrogen assimilation. Applications of novel statistical tools in conjunction with LC-MS analysis indicated that the insecticide carbofuran can induce large changes of endogenous metabolomes in tomato fruits [98].

Interactions among plants, pest insects, and pathogens are another interesting subject of metabolomics. For example, *B. rapa* leaves, attacked by the

diamondback moth (*Plutella xylostella*) or beet armyworm (*Spodoptera exigua*), differentially accumulated alanine, threonine, glucose, sucrose, feruloyl malate, sinapoyl malate, and gluconapin, depending upon the insect species and the developmental stages [99].

Metabolomics with aquatic plants or algae are scarce, although their environmental significance is as important as their terrestrial counterparts. Representative examples include metabolomic evaluations of the green algae *Chlamydomonas reinhardtii* under nutritional stress [100, 101]. This microalga is known to produce hydrogen under anaerobic conditions. Recent studies indicated that a large portion of metabolites are differentially expressed, depending upon the deprived nutrients. Time-resolved assays suggested that the kinetic responses also differ among nutrients. For example, the response to phosphorus deprivation was slower than to sulfur or nitrogen [100]. Matthew et al. [101] found that hydrogen overproduction in *C. reinhardtii* is induced by sulfur-deprivation through metabolic re-programming or a build-up of the toxic fermentative products formate and ethanol. An excellent review has been published about metabolomic studies of marine macroalgae [102].

The most notable trend in recent plant metabolomics is integrated omics. By integrating transcriptomics, proteomics, and metabolomics, characteristic differentiation of metabolomes was identified as a defensive response in rice seedling (*Oryza sativa*) [103]. These findings provided insights into metabolic responses against stresses.

Another interesting advance in metabolomics is the development of novel data-mining technologies. Sato et al. [104] investigated rice foliage metabolomes through correlative approaches between metabolites and regulatory networks. In general, most metabolomic research gives numerical data with no correlative information among metabolites. Correlations among metabolites, genes, and proteins will give more comprehensive understanding of stress response.

Metabolomics in Microbiology

There have been a limited number of publications on metabolomics of microorganisms, particularly under stressed conditions. Microorganisms are more prone to metabolic changes than higher organisms because they

are directly exposed to the stimuli. Tweeddale et al. [105] reported that *Escherichia coli* underwent interesting metabolic changes under oxidative stress. Paraquat, a well-known respiratory inhibitor, can induce the up-regulation of several oxidative stress-related proteins and an increase of branched amino acid and sulfur-containing metabolite pools (e.g., valine and glutathione) [105].

Elucidation of mode of action is a very important subject in pesticide and drug discoveries. However, this can be a laborious and time-consuming task because a biological system contains a wide array of metabolites, proteins, and genes. Metabolomics is a high throughput, comprehensive analytical option for this purpose. The first example can be found in metabolic phenotyping of the yeast *Saccharomyces cerevisiae* mutants [9]. Metabolic patterns of *S. cerevisiae* treated with 10 commercial fungicides were differentiated via metabolomics, where two large clusters were derived according to the inhibitory activities [106]. Such a study was extended to non-model diatoms under iron starvation [107].

Heavy metals are stressors to microorganisms [107–109]. Heavy metals can induce metabolic changes in glutathione and osmolytes (e.g., glycine and betaine) as well as other metabolites. Among these metabolites, glutathione and betaine are commonly found in stressed plants, animals, and microorganisms. Recent studies with the anaerobic bacteria *Shewanella oneidensis* indicated that the overall metabolisms are highly stable even under extremely stressed conditions. Only part of the metabolic pathways (e.g., sulfur amino acid metabolism) gave rapid responses to the external toxicants [110].

Bacterial metabolomics with environmental relevance were recently reported [111, 112]. For example, the bacterium *Sinorhizobium*, upon exposure to environmental contaminants, has shown a characteristic shift to a more hydrophobic fatty acid profile. In addition, the amount of storage metabolites such as polyhydroxyalkanoates decreased under stressed conditions. A large portion of the metabolites decreased, while trehalose, branched amino acids and sulfur-containing acids accumulated. The results indicated that oxidative stresses and metabolic confinement are a response to nutritional deficiency [112].

A recent trend in microbial metabolomics is integrative omics. Intracellular metabolism of benzoic acid in the white-rot basidiomycete *Phanerochaete chrysosporium* was investigated at the proteome and metabolome levels. Up-regulation of aryl-alcohol dehydrogenase, arylaldehyde dehydrogenase, and cytochrome P450s suggested that these enzymes play key roles in benzoic acid metabolism. Intracellular metabolic shifts to the TCA cycle indicated activation of heme biosynthesis and the production of NAD(P)H. Both metabolites are the most important components of oxidative enzymes. The analyses also indicated the role of trehalose as a storage disaccharide and the presence of an alternative energy-producing pathway [113]. The bacterium *Streptomyces tenjimariensis* can produce istamycins, displaying a high potency against many Gram-negative and Gram-positive bacteria. Denery et al. [114] used metabolic profiling and polymerase chain reaction (PCR) techniques as a means of studying the growth of *S. tenjimariensis*. The study showed metabolite profiles that are unique to growth phase and signify how they can be used for further applications in the understanding of microbial metabolism, antibiotic production, and physiology.

Future Directions

Metabolomics is an emerging field. It has started to play an important role in biological sciences, particularly in systems biology and biomarker studies. However, its applications are still limited by many challenges in methodologies and applications. A noteworthy example is “lipidomics,” a branch of metabolomics focusing on lipids. A tremendous amount of research has been done with hydrophilic metabolites, whereas applications of lipidomics are very limited. It is no doubt that lipidomics will become an important tool in lipid research, particularly concerning the physiological significance and function of lipids. The metabolome is the down-stream product of genes and proteins. Metabolomics alone can give the final outcome of specific stresses, but does not provide direct information on the up-stream changes such in genes and proteins. This is both the strength and weakness of metabolomics and, therefore, integrated omics approaches seem to be inevitable. Many examples of integrated omics have recently been published, and this

approach will become more popular in the future. Such a trend will improve both the quality and quantity of metabolomic data, especially in environmental toxicology. Technological challenges include data mining, analysis, and synthesis (i.e., data dimensionality and processing). Comprehensive networks of metabolites, proteins, and genes provide an overview and in-depth understanding of biological events and processes. Metabolomics tells what is happening at the metabolic level, provides direct evidences of stress, and will therefore contribute significantly to environmental toxicology.

Acknowledgments

This work was supported in part by grants from the US Fish and Wildlife Service and Hawaii Energy and Environmental Technologies Initiative Award No. N00014-09-1-0709. We thank Adam Baker and Margaret R. Ruzicka for comprehensive review of this chapter.

Biochemical conversion Conversion of biomass based on biological processes into energy carriers and/or energy.

Bioenergy Bioenergy is defined as energy from biomass.

Biofuel Biofuel is a fuel produced directly or indirectly from biomass.

Biomass From a scientific and technical point of view, biomass is defined as material of biological origin excluding material embedded in geological formations and/or transformed to fossil.

Conversion route A conversion route is defined as the overall processes of production, provision, handling, and processing biomass to the point of delivery of the useful energy.

Physicochemical conversion Conversion of biomass based on physical and/or chemical processes into energy carriers and/or energy.

Thermochemical conversion Heat induced conversion of biofuels into energy carriers and/or energy.

Definition of the Subject

Biomass, a renewable source of energy, has been used since the beginning of human culture. Until the introduction of coal, crude oil, and natural gas, wood and other forms of biomass were the most important sources of energy available to humans. Today, biomass accounts for roughly 10–12% of the global primary energy consumption and, at a time of politically forced and environmentally needed greenhouse gas mitigation and an expected shortage in fossil fuel energy resources, this energy carrier is becoming more and more important. The goal of this chapter is to give an overview of the technical possibilities and challenges of energy provision from biomass. First, the various biomass sources available are discussed briefly. Next, available conversion routes are presented, showing the broad variety of possible options to provide heat, electricity, and/or transportation fuels. Based on these fundamentals, the thermochemical, physicochemical, and biochemical conversion possibilities are discussed. For these three options, in addition to the basics, the technical possibilities are briefly presented to indicate the current status of technology. Finally, future directions are discussed.

Introduction

Biomass currently provides 10–12% of global primary energy. Due to geographical, economic, ethical, and climatic differences, as well as different frame conditions within the energy system, the share of bioenergy in relation to the total energy consumption differs widely between different countries, ranging from less than a few percent in some industrialized countries like the United Kingdom to significantly more than 50% in some developing countries in Africa and Asia. Nevertheless, biomass is by far the most important

renewable energy source in most countries, being significantly larger in use than the second largest source, hydropower. The energy from these sources – the oldest fuels utilized by humans – is even larger in absolute terms than the energy from one of the newest – nuclear fuels.

Solid biofuels dominate the global biomass picture. It is safe to say that significant shares of the world's population still rely on solid biofuels for most of their energy. This situation has not changed since the mastery of fire some hundred thousand years ago. This is due to the relatively low cost of and easy access to solid biofuels such as wood, dried dung, and crop residues (like straw) in rural areas of developing countries where more than one third of humanity lives. In addition, other bioenergy carriers such as wood pellets, bioethanol, and biogas play an increasingly important role in some regions in developing as well as in industrialized countries, where their costs and access compare favorably with fossil fuel-based energy in the context of the frame conditions defined by the respective governments. Additionally, the potential of the biomass resources available to humans is significant on a worldwide scale. Sustainably produced solid, liquid, and/or gaseous biofuels also have the advantage of being climatically neutral and environmentally sound compared with other sources of fossil fuel energy, which has led to a resurgence in interest in biomass throughout the world.

Compared with other renewable sources of energy, biomass has the advantage that it can be used for heat provision, electricity production, and the provision of liquid and gaseous fuels for transportation purpose. And within all of these markets, biomass already plays a certain and increasing role within the global energy system. This development will accelerate in the years to come, with an increasing energy price level.

Heat from biomass is used for cooking and/or space heating. While cooking with (solid) biofuel is rare today in industrialized countries (with the exception of outdoor barbecue), this is still the “classical” bioenergy application in most developing and threshold countries. It is likely that this market will continue to grow in the years to come due to a significant increase in population, especially in these countries. Heat provision from biomass for domestic and industrial applications is realized in all countries worldwide,

but generally more in rural areas of countries during the cold season. This heating market is also likely to grow in the future, especially if crude oil prices continue to stay relatively high or increase further. Additionally, due to the political goal to reduce greenhouse gas emissions and the development of highly efficient and more comfortable combustion technologies, heat provision from solid biofuels is undergoing a renaissance in some industrialized countries.

Demand for electricity has increased greatly in recent years in all countries. Even though the use of electricity is widely accepted, the provision of electrical energy can be controversial in some countries with a strong environmental movement. The debate about the pros and cons of nuclear power and the discussion about the contribution of electricity from hard coal and lignite to the global greenhouse effect are only two examples. Therefore, the generation of electricity from biomass is seen in some countries as a promising alternative, contributing in parallel a more indigenous and safer electricity provision, as well as increasing prosperity in rural areas. For this reason, it can be expected that the production and provision of electricity from biomass will significantly increase in the years to come. Within combined heat and power (CHP) plants, electricity generation can be combined in an ideal way with heat provision by maximizing the overall energetic efficiency. With limited available biomass resources, this option is gaining more importance, especially in countries with a high heat demand due to cold winters. For this reason, a considerable and growing share of the increasing electricity production from biomass is realized in CHP plants, depending on the frame conditions set by the respective government.

Production of transportation fuels from biomass is also increasing. The need for mobility is dramatically growing on a worldwide scale, particularly in some of the emerging economies in Asia. Therefore, finding ways to provide cheap, technically mature, climatically sound, and environmentally benign fuels based on renewable energy in general and biomass in particular is an extremely active endeavor. Therefore, the research and development (R&D) activities in this field have increased significantly in recent years in most of the Organization for Economic Co-operation and Development (OECD) countries, as well as in selected developing countries and emerging economies; the

main challenge is to produce more liquid and/or gaseous transportation fuel from the limited available biomass. This challenge is the same worldwide, but, so far, only Brazil and the United States produce liquid biofuels (ethanol) for transportation purposes on a large scale with a measurable impact within the energy system.

In the following sections, the available biomass resources are discussed, and the various conversion routes of biomass – thermochemical, physicochemical, and biochemical – into useful energy will be described.

Biomass Sources

Biomass consists primarily of the elements carbon (C), hydrogen (H), and oxygen (O) (Table 1). Additionally, significant amounts of trace elements can be found in some types of biomass. For example, straw may contain fairly high amounts of chlorine (Cl) and/or silicon (Si) and rapeseed contains a relatively high amount of nitrogen (N). These trace elements can sometimes cause problems during the conversion into an energy carrier and/or useful energy. For example, during combustion chlorine might cause high temperature corrosion in boilers, silicon can lead to boiler slagging, and nitrogen can be responsible for high NO_x emissions, which are limited in most countries.

In most practical applications, the energy content of biofuel is best described by the net calorific value. Besides the chemical composition of the organic material, net calorific value is influenced by the water content of the biomass. Due to the fact that the chemical composition of most solid biomass fractions does not vary significantly (Table 1), the net calorific value related to the dry matter is similar for most of the biomass streams used (e.g., wood, straw) for the provision of solid biofuels. This might be different for liquid or gaseous fuels provided by a more or less complex conversion process based on heat-induced (i.e., thermochemical conversion) and/or biological processes (i.e., biochemical conversion).

Figure 1 shows that the net calorific value of wood decreases from approximately 18.5 MJ/kg dry matter with increasing water content. The net calorific value is zero at water content of approximately 88%. Normally, the water content of air-dried wood is between 12%

Biomass as Renewable Source of Energy, Possible Conversion Routes. Figure 1

Net calorific value of wood depending on the moisture content [1]

and 20%, yielding a calorific value between 13 and 16 MJ/kg. Freshly harvested wood is characterized by a water content of about 50% or more. A significantly lower net calorific value is the result. This is the reason why wood is usually dried with solar energy.

Independent of the fact that the heating value is more or less similar for organic matter used for the provision of solid biofuels, there is a huge variety of different biomass material streams available to be used as a source of energy. The properties of these biomass fractions define the conversion routes that are technically possible and economically feasible. The most important biomass fractions are discussed below.

Woody Biomass

Wood is the “classical” solid biofuel, used for thousands of years (basically since the mastery of fire by humans). This is especially true for wood from forests. In most countries fire wood as an energy carrier is a product from forestry management like timber for the use as a raw material (e.g., for construction purpose). In addition to forest wood, woody biomass to be used as a source of energy can also be grown on agricultural land. To maximize the average yield and thus minimize the land needs, tree plantations are harvested

after a couple of years (i.e., short rotation coppice). Beside this, wood fuel can be derived from production and consumption of wood and wood products as a residue, a by-product, and/or a waste material all along the supply chain of wood as a raw material as well as pulp and paper products (Fig. 2). For example, thinning wood and forest residues are produced as a by-product during the production of stem wood as a raw material for case goods and furniture production. Industrial residual wood, bark, and wood dust are by-products and/or waste materials resulting from the production of timber and the manufacturing of wood structures or wood products. At the end of the product lifetime and after recycling of some wood fractions (such as old furniture or roof timbering, chipboards), partly contaminated woody material and waste wood remain, which can be used as fuel.

Herbaceous Biomass

The available organic material flow from herbaceous biomass can be subdivided into herbaceous energy crops grown specifically as biomass fuels (like whole crop cereal, rape or sunflower seed, *Miscanthus*, switchgrass, sugar cane, maize silage) and by-products of the production of non-energy products (like straw produced during the production of cereals). The latter arise primarily from the production processes for the provision of food, fiber, and fodder (e.g., the production of grain is necessarily connected with the production of straw). The same is true for the production of crops with special substances (e.g., specific oily substances, specific scents) to be used as a raw material (e.g., in the chemical industry, for the production of pharmaceuticals). Additionally herbaceous biomass is also produced, for example, in conservation areas, parks, cemeteries, gardens, and on roadside areas.

Other Biomass

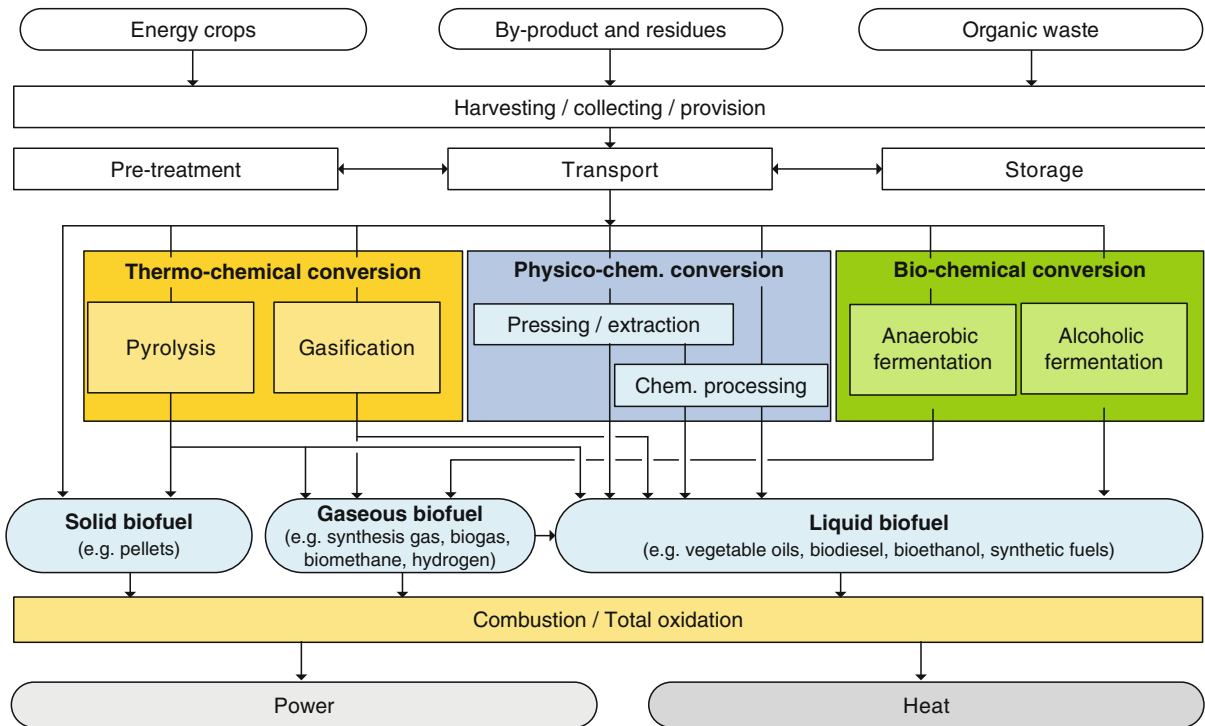

Various other organic materials usable as a source of energy are available within the overall economy, including by-products and waste materials from agriculture (e.g., animal manure), industrial food and fodder processing processes (e.g., slaughterhouse residues, vegetable waste, olive and fruit pits), food

Material flow of wood within the overall economy [1]

Conversion Routes

The different possibilities to provide secondary energy carrier with more promising fuel characteristics compared with mechanically treated biomass (like wood chips, wood logs, pellets, silage, organic waste) can be subdivided in options based on heat induced processes (i.e., thermochemical conversion), on biological processes (i.e., biochemical conversion), and on physico-chemical processes (physicochemical conversion). These

Biomass as Renewable Source of Energy, Possible Conversion Routes. Figure 3

Possibilities to provide heat and/or power from biomass (Based on [1])

different options are discussed briefly below. But before that the provision of biomass free conversion plant is analyzed.

Design of Typical Conversion Routes

In general, the conversion route describes the pathway from the production of the energy crops, the provision of residues, by-products, and/or wastes at the place of origin until the provision of the biomass in a predefined form at the gate of the conversion plant, the provision of secondary energy carrier (e.g., solid, liquid, or gaseous fuel, district heat), the provision of final energy (e.g., heat, electricity), or the provision of useful energy (e.g., heat, power). Thus, such a conversion route describes the overall life cycle from the production respectively the come up of the organic matter (i.e., the primary energy) up to the provision of the secondary, useful, or final energy.

The overall goal of such a conversion route is to meet a varying demand of final or useful energy with a predefined security of supply. To reach this goal, appropriate conversion plant(s) with a reliable technical performance are needed as well as the necessary amount of biomass of a predefined quality.

Each conversion route consists of the life cycle steps of biomass production, and each of these steps is composed of various single technical processes. For example, biomass production requires preparation of the seed bed, distribution of fertilizer as well as plant protecting agents, and selected cultivation measures.

Because the different life cycle stages of a biomass conversion route normally do not take place at the same location, the distances have to be travelled by various means (e.g., trucks, pipelines, conveyor belts). The choice of transportation is – beside technical aspects – mostly based on economic considerations.

A specific conversion route is thus very much defined by the frame conditions fixed by the available biomass

(supply side) on the one hand and the requested provision of the final and/or useful energy (demand side). Additionally, technical, economic, and environmental (as well as administrative and/or legal (and emotional)) aspects significantly influence the realization of such a conversion route. For example, the choice for a specific conversion technology is influenced by the desired final or useful energy carrier (e.g., thermal energy, mechanical energy, electrical energy) and the (cheap) locally available biomass. The environmental standards defined by governments (e.g., emission limits, noise limits, odor regulations, waste disposal directives) and the economic frame conditions pertaining to the specific circumstances define the design and practical realization of such a biomass conversion route. Additionally, the disposal of waste produced by different processes within the overall route (e.g., digested animal manure leaving the biogas plant, ash remaining after the combustion of wood pellets) might influence the layout of such a route dramatically. Based on the consequences resulting from the thus necessary (expensive) waste disposal, a certain demand could be formulated to the quality of the biomass (e.g., water content, dimensions, impurities) used within such an overall conversion route. To achieve the desired effects, the quality of the used biomass has to be guaranteed within the overall route, with the consequence that there might be the need to include additional processing steps in the provision chain.

Biomass availability can vary throughout the different seasons of the year, which has to be taken into consideration as energy demand changes over time. This means that certain storage options (e.g., wood chip storage, heat storage) have to be included within the overall chain to ensure a predefined degree of security of supply.

Additionally, the developed conversion route matching all these demands has to be economically viable under the frame conditions defined by the investor, the local frame conditions, and the government, have the opportunity to receive the required legal authorization (if applicable), and – last but not least – be socially and emotionally acceptable to the people living close to the conversion plant. And – which makes the design, successful operation, and ongoing optimization of such a conversion route even more challenging – different players with different backgrounds and understanding (like farmers, power plant operators,

investors) have to communicate and interact successfully with each other as well as with the representatives of the (local) regulatory authority. Thus a biomass conversion route is defined by technical as well as various nontechnical aspects. This makes the set-up of new chains exiting and demanding.

Conversion Options to Provide Secondary Energy Carriers

The conversion of biomass (i.e., organic material of very different origin) into solid, liquid, and/or gaseous secondary energy carriers can be realized via heat-induced processes (i.e., thermochemical conversion), via transformation by bacteria (i.e., biochemical conversion), and/or via physicochemical processes. These conversion processes are, in most cases, the “heart” of such a conversion route. Below, an overview is given to explain the most important possibilities as well as the main differences.

Thermochemical conversion. Biomass can be converted into useful energy or into secondary energy carriers using conversion processes based on heat.

During the “classical” combustion of biomass for the provision of heat and/or electricity, the biomass is fully oxidized, basically with oxygen from the surrounding air, by releasing heat. Various chemical processes are realized during this oxidization. These processes take place in parallel at the same place. Due to the frame conditions defined by the involved combustion technology and its defining control parameters, the chemical reactions can be influenced to a certain degree to minimize the creation of unwanted substances harmful to the environment.

Alternatively, the thermochemical conversion can be split up and realized at different places. Within such conversion processes, solid biomass is mixed under defined conditions (pressure, temperature, etc.) and high temperatures with an oxidizing agent (e.g., air, water) clearly below the stoichiometric concentration. This enables them to be converted into solid, liquid, and/or gaseous secondary biofuels to be used somewhere else. The chemical processes underlying the respective conversion routes are based on the same fundamental reactions. But the composition of the resulting secondary energy carrier varies depending on, for example, the involved technology, the selected

process parameters, the catalyst involved (if applicable), and the type of biomass used.

In gasification, the solid biofuels are converted as completely as possible into an energy-rich producer gas or synthesis gas and thus into a gaseous secondary energy carrier. After expensive cleaning processes, the gas can be used directly without any further chemical transformation, for example, in an engine, a turbine, or even a fuel cell to provide heat and/or electricity. Alternatively, the gas can undergo a subsequent synthesis process to be converted into a liquid or gaseous biofuel with clearly defined properties (e.g., Fischer-Tropsch diesel, synthetic natural gas (biomethane), hydrogen) for easy use within the transportation sector, for example.

In pyrolysis, solid biomass is converted solely by the (short- or long-duration) application of heat into solids (charcoal), liquids (bio-crude oil), and gases (e.g., CO, H₂, CO₂).

- The aim of fast pyrolysis or intermediate pyrolysis processes is to obtain a maximum yield of liquids (i.e., bio-crude oil). The by-products – e.g., combustible gases and charcoal – can be used to provide the energy needed for the conversion process and/or as a raw material (e.g., active coal as a filter medium). The produced pyrolysis oil or bio-crude oil has to be refined and can then be utilized either as feedstock for the chemical industry and/or as liquid fuel for engines and/or turbines.
- The goal of slow pyrolysis processes is it to convert solid biomass into a solid energy carrier with clearly defined characteristics (i.e., charcoal) and thus improved combustion characteristics compared to the feedstock. This solid carbon can then either be used as a more pleasant source of energy (e.g., for daily cooking in developing countries and for leisure activities (barbecue) in industrialized countries) or as a raw material, for example, in the chemical industry (e.g., as a filter material).

Thus, based on such a thermochemical conversion – besides the provision of heat and electricity – the direct and/or indirect production of solid, liquids and/or gaseous secondary energy carriers is also possible.

Physicochemical conversion. This conversion pathway is used to produce liquid biofuels from organic matter containing oils and fats (e.g., rapeseed,

oil palm fruits, sunflower seeds). The oil is separated from the seed, for example, by pressing and/or extraction based on existing process technology well known for centuries. Afterwards the oil is cleaned with existing technical processes to meet the given predefined product standards. The clean vegetable oil can be used as an energy source in its straight form (if the engine is able to burn such a relatively inhomogeneous fuel characterized by considerable differences from conventional diesel fuel) or after a chemical treatment conversion (e.g., transesterification with methanol to fatty acid methyl ester [FAME]). Alternatively, the vegetable oil can be treated with hydrogen (i.e., hydrogenation to hydrogenated vegetable oil [HVO]) or processed together with crude oil in existing oil refineries to provide a fuel with clearly defined characteristics meeting the requirements for the existing transportation fuels (e.g., diesel fuel specification, kerosene specification).

Biochemical conversion. In this group of conversion processes using microorganisms, organic material is split into fragments that could be used to provide new chemical compounds. Hence, this conversion is based on biological processes.

- During alcoholic fermentation, the sugar, starch, and cellulose contained in some types of biomass is transformed into ethanol, which, after distillation and dehydration, can be used as pure alcohol or blended with conventional gasoline to fuel engines and/or turbines.
- In anaerobic fermentation, organic matter is converted into biogas (slightly more than 50% methane; the rest is mainly carbon dioxide). This gas can be used in CHP generating stations to produce electricity and heat or, alternatively, after further processing, upgrading, and where necessary distribution through the existing natural gas grid, used to fuel vehicles designed to use of natural gas.
- Other biochemical conversion options currently under discussion include the production of, for example, hydrogen from some specific types of organism living in an aqueous environment.

Thermochemical Conversion

Thermochemical conversion describes the conversion of preferably solid biofuels into secondary energy

carriers, into final energy, and/or into useful energy based on heat-induced processes. For this conversion option, the chemical basics are discussed below. Then, the solid biofuels usually used within such conversion units are briefly described. The technologies for direct combustion, pyrolysis, and gasification are then presented.

Basics

During the complete thermochemical conversion, solid biofuels are oxidized primarily to carbon dioxide and water by releasing heat. Equation 1 shows the approximate process for wood, which can be described chemically as $C_nH_mO_p$.

The complete thermochemical conversion of solid biofuels consists of the following steps: heating and drying, pyrolytic decomposition, gasification, and oxidation (Fig. 4). Within a “classical” biomass combustion unit for heat provision, these four different thermochemical conversion steps are realized at the same place and at the same time. Equation 1 is

performed – via different intermediate steps as discussed below in detail – completely (i.e., full oxidation).

Alternatively to overall oxidation (Eq. 1) can be split and performed at different points of time and in various locations. For example, such an interruption can be realized after the steps of heating and drying as well as pyrolytic decomposition; gasification and oxidation take place within another device (i.e., in a different place) and at a different point in time. Another possibility is it to split the process after three intermediate conversion steps (i.e., heating and drying, pyrolytic decomposition, and gasification).

These different steps of the thermochemical conversion are explained below.

Heating and drying. Before any chemical reaction of the organic material (e.g., wood, straw, rice husks) can take place, the biomass has to be heated up. During this endothermic process, water is evaporated at temperatures up to approx. 200°C. Below roughly 100°C free water, and above this temperature, water bound to the molecule structure of the solid biomass, is released as vapor. The water may leave the organic material and thus the reaction zone. Alternatively and/or additionally, this water vapor may act as an oxidizing agent within the processes taking place within subsequent

Biomass as Renewable Source of Energy, Possible Conversion Routes. Figure 4
Processes realizing the thermochemical conversion of solid biofuels [1]

conversion steps (e.g., gasification). This process of heating and drying requires energy (i.e., the process is endothermic).

Pyrolytic decomposition. Organic material consists of large macromolecules. If they are sufficiently exposed to thermal energy they are thermally decomposed in smaller chemical molecules (i.e., chemical compounds with only few elements). The products of this pyrolytic decomposition of the solid biomass (i.e., the so-called volatile compounds) are driven out of the organic material. This process is endothermic (i.e., energy is needed) and requires no oxygen.

For example, for wood the pyrolytic decomposition starts at about 200°C with the decomposition of hemicellulose, which is a part of wood material. The decomposition of cellulose (another component of wood) takes place at temperatures of 300°C and higher. Finally the decomposition of lignin (another component of wood) takes place at even higher temperatures. The yield and composition of the volatiles vary depending on the temperature and velocity at which the pyrolytic decomposition is realized. Additionally, the composition of the solid organic material (e.g., wood, straw, leaves) might have an influence overlaid by possible catalytic effects. In general, however, the result of the pyrolytic decomposition is very much the same for different types of solid biomass under comparable process conditions.

During this process, the macromolecules that biomass consists of are fragmented due to the influence of the heat by a similar set of complex decomposition reactions. As a result of such decomposition processes at relative high temperatures, the following components are formed:

- Volatile compounds, such as hydrogen (H₂), carbon monoxide (CO), methane (CH₄), carbon dioxide (CO₂), nitrogen (N₂) and steam (H₂O)
- Carbon rich solid fraction (char)
- Low molecular weight organic compounds and high molecular weight (condensable) compounds (i.e., liquid products)

Gasification. In order to convert the solid carbon remaining after the pyrolytic decomposition into a gas, an oxygen containing gasification agent such as air, pure oxygen, or water is required. Based on this, at temperatures between 700°C to 1,500°C, the solid

carbon as well as gaseous products (CO, H₂, CH₄) are oxidized as follows (Eqs. 2–6):

Partial oxidation of solid carbon:

Complete oxidation of solid carbon:

Oxidation of carbon monoxide:

Oxidation of hydrogen:

Oxidation of methane:

Additionally, balance reactions take place. The most important are the reduction of CO₂ to CO (Boudouard reaction) and of H₂O to H₂ (heterogeneous water gas reaction). Also, carbon can be transformed to CH₄ (Eqs. 7–9).

Boudouard reaction:

Heterogeneous water gas reaction:

Heterogeneous methane production:

These and other reactions take place during this gasification conversion step. Depending on the given conditions within the reaction zone (i.e., temperature level, pressure, gasification agent, catalyst (if applicable),

gasification technology), different chemical reactions might contribute in a varying share to the overall gasification. The consequence is that the composition of the gas might be different. Therefore, the gas composition can be influenced to a certain degree by setting the frame conditions within the reactor where these reactions are taking place. For these reasons, during gasification, sometimes energy is needed and sometimes energy is released.

Additionally, some of these reactions can also take place during the pyrolytic decomposition at higher temperatures because the biomass itself contains oxygen. Therefore, the borderline between these two conversion steps can not always clearly defined.

Oxidation. Within this last step of the thermochemical conversion, the gaseous products produced during the previous steps are fully oxidized to carbon dioxide and water. In this chemical reaction, energy is released (i.e., they are exothermic). After the performance of this step, Eq. 1 showing the overall reaction equation is fully realized. At this point the biomass is fully oxidized. Under these conditions, the excess air ratio is 1.0 or above (the excess air ratio is defined as the ratio between the amount of oxidizing agent fed to the conversion process and the amount of oxidizing agent needed to fully oxidize all reaction products; per definition the excess ratio is 1.0 if the conversion process is realized exactly stoichiometrical as shown in Eq. 1).

Solid Biofuels

For thermochemical conversion processes, usually solid biomass is available on the local, regional, and/or global markets. To allow for a highly efficient and an environmentally sound conversion, they should match easily and reliably the needs of the conversion units (and vice versa).

Based on this precondition for sustainable biomass use, two approaches are possible: (a) solid biofuels with very narrowly defined and preferably standardized fuel characteristics and (b) solid biofuels with very low respectively no requests on the fuel characteristics (i.e., no standardized fuel characteristics). The former option has the consequence that a high technical and thus resulting economic effort is needed to provide such clearly defined solid biofuels (as is the case for wood pellets). The advantage is that the fuel

characteristics can be adapted accurately to the specification of a specific type of conversion units (and vice versa). For the latter possibility, it is exactly the other way around. Here, the effort to produce the fuel is in general relatively low (e.g., manually produced wood logs, shredded demolition wood). Thus, the technical effort within the conversion plant is significantly higher because it is technologically more demanding to convert fuels with strongly varying fuel characteristics efficiently, securely, economically, and environmentally sound into useful energy compared with the former option.

The choice of which combination will be realized on the market is influenced by the user group, the installed capacity, the environmental demands defined by the responsible legal body, the economic frame conditions, the required comfort level, and the competing energy carrier as well as manifold other reasons.

For the reasons outlined above, currently the following different types of solid biofuels can be found on the local, regional, and global biofuel market.
